In this research, we introduce NeuroCamTags, a battery-free platform designed to detect a range of rich human interactions and activities in entire rooms and floors without the need for batteries. The NeuroCamTag system comprises low-cost tags that harvest ambient light energy and utilize high-frequency modulation of light-emitting diodes (LEDs) for wireless communication. These visual signals are captured by an available neuromorphic camera, which boasts temporal resolution and frame rates an order of magnitude higher than those of conventional cameras. We present an event processing pipeline that allows simultaneous localization and identification of multiple unique tags. NeuroCamTags offer a wide range of functionalities, providing battery-free wireless sensing for various physical stimuli, including changes in temperature, contact, button presses, key presses, and even sound cues. Our empirical evaluations demonstrate impressive accuracy at long ranges up to 200

1 Introduction

For decades, smart environments have promised to improve our lives by inferring context, actions, and activities in various settings, from public areas and offices to homes, workshops, factories, and healthcare centers. To achieve this vision, one of the most commonly adopted methods for making dumb environments “smart” is using embedded cameras. However, only using cameras is limited by the richness of the data that they capture. For instance, most camera approaches capture just visual information, and therefore, they are fused with data from different sensing modalities to capture human touch, temperature, audio, pressure, etc. However, using these smart devices (both cameras and sensors) for perpetual sensing of human environments has not yet been realized due to two major issues: power and privacy. Smart devices such as cameras and sensors are defined by short battery lifetimes, high maintenance costs, and rapid obsolescence, contributing to the explosion of electronic waste in the past decades [10, 18]. Replacement of billions of batteries (per year) that power these sensors would be unsustainable and have high costs. The ecological impacts of computing with batteries have become clearer and clearer [16].

Fortunately, emerging paradigms for cameras, such as neuromorphic cameras [13, 35], present numerous benefits, including low-power operation, extremely rapid response times down to microseconds (μ s), and enhanced privacy due to their reduced data capture compared to standard cameras (see Figure 1 C). In our research, we introduce *NeuroCamTags*—a hardware platform for building a collection of battery-free interactive devices that harness the unique capabilities of neuromorphic cameras to foster eco-friendly intelligent spaces. We designed NeuroCamTags as solar-powered devices capable of sensing user interactions and wirelessly transmitting data via high-frequency LED modulation. We then detect these light signals over considerable distances using neuromorphic cameras due to their superior high dynamic range (HDR) and rapid temporal resolution compared to the frame rates and HDR capabilities of traditional cameras. For example, we show a range of battery-free wireless sensors and interactive devices in Figures 1 and 2. NeuroCamTag sensors are capable of monitoring object use, environment variables, and user interaction. In Figure 2, we see the temperature of the glue gun held by a user in the workshop as far away as 70 feet from the camera in our 160 feet by 100 feet maker space environment.

In this paper, we describe the design and implementation of NeuroCamTags: circuit designs, sensors, energy harvesting, and energy management methods. We investigated modulation methods for embedding sensor data, including On-Off Keying (OOK) and frequency modulation (FM), optimized for optical wireless communication with neuromorphic cameras. We further discuss the software pipeline developed for demodulation, signal processing, and the application of machine learning to interpret the data acquired by neuromorphic cameras for the detection of NeuroCamTags and the analysis of user activity. We present our experimental findings on the operational efficiency of NeuroCamTags in various scenarios—covering diverse distances, lighting conditions,

Fig. 2. Human interaction and sensing A. Playing an interactive game of pong with multiple battery-free game controllers. B. Sending temperature sensor reading and localization information wirelessly over a long range (70 feet)

and angles of view, as well as their application in assorted intelligent settings such as workshops and kitchens. Our system can recognize user interactions with an accuracy of 96.3% and maintains a false positive rate of 3.4%. Our studies also reveal the capability of our tags to function effectively from distances up to 200 feet. Furthermore, we examine the specifics of power usage of our devices, noting the minimal light levels (500 lux) required for battery-free operation and the data transmission rates needed for functionality. We conclude by showcasing 11 practical applications we developed, demonstrating the broad capabilities and potential uses of NeuroCamTags.

Overall, we believe this work introduces a new sensing approach for smart environments with unique strengths to contribute to human-computer interaction (HCI) researchers. We make the following contributions to this work:

- An end-to-end system including hardware, and signal processing algorithms, for battery-free smart environment sensing based on neuromorphic cameras.
- Custom circuits that integrate sensing, energy harvesting, voltage regulation, and embedded computation. These circuits are uniquely designed for both analog and digital visible light communication (VLC) with neuromorphic cameras, optimizing power consumption and operational range.
- Empirical Evaluation of the usable range, distance, power and transmission speed of NeuroCamTags under various conditions
- A proof-of-concept demonstration and technical validation of activity detection in two smart environments instrumented with NeuroCamTag wireless sensors.

2 Background and Related Work

Neuromorphic vision sensors are inspired by the design of the human eye's rods and cones in detecting light. Similar to the human eye, image signals are processed individually across pixels in these sensors. Unlike standard RGB cameras that capture entire scenes, neuromorphic cameras monitor changes in brightness (polarity) for each pixel, doing so with remarkable speed and minimal delay. They offer six key benefits for vision-based sensing compared to traditional cameras:

Pixel-level Independence: Each pixel in a neuromorphic camera operates independently and asynchronously (see Figure 1 C). Instead of capturing frames at a fixed rate, each pixel in the sensor detects changes in intensity independently and only responds when it sees a change.

Low Latency: Since pixels respond to changes immediately, the latency can be extremely low, often in the order of microseconds, significantly faster than the milliseconds typical of conventional cameras.

High Dynamic Range (HDR): Event cameras are known for their high dynamic range, often exceeding 120 dB compared to about 60-70 dB for standard cameras. This enables them to work well in both very bright and very dark environments without the typical over or underexposure problems.

Power Efficiency: By only sending information when changes are detected, event cameras typically consume substantially less power [12], making them efficient for edge IoT applications.

Reduced Data: As they only output data when changes in the scene occur, event cameras can generate far less data than traditional cameras, which capture the entire scene at regular intervals. This can reduce storage and processing requirements.

Temporal Resolution: The asynchronous nature of the pixel response allows for very high temporal resolution, capturing quick changes in a scene that might be missed by the slower frame rates of traditional cameras.

These advantages underscore the potential of neuromorphic cameras for energy efficient sensing and visible light communication. An array of recent related work has explored the use of neuromorphic camera for diverse applications. For instance, work by Kueng et al. [22], Craig et al. [19], and Zhou et al. [64] has showcased event cameras in visual odometry and tracking mobile ground robots. In the realm of driver monitoring systems, Shariff et al. [46] have demonstrated the effectiveness of event cameras even under dynamically changing scene lighting. Mueggler et al. [29] achieved 6-DOF pose tracking for high-speed maneuvers using event-based methods.

The field of non-contact signal acquisition and fault diagnosis has also advanced significantly, with Guang et al. [17] introducing a method for integrating machine-generated event data into precise vibration signal extraction and fault diagnosis. In emergency detection and alerting systems, Costa et al. [8] developed systems for urban, agricultural, and industrial settings using neuromorphic cameras.

Pertinent to our work, Chen et al. [7] created a system for accurately identifying high-frequency flickering LEDs in indoor positioning using neuromorphic cameras. Wang et al. [54] developed a beacon system with flickering high-frequency LEDs for robotic communication. In the field of human-computer interaction, neuromorphic cameras have been used for gesture detection [2] and, more recently, for activity recognition from an egocentric perspective [34]. For an in-depth understanding of neuromorphic cameras, we recommend the work by Gallego et al. [14], which discusses camera principles, sensors, applications, challenges, and future directions in machine perception.

To the best of our knowledge, our work is one of the first to employ neuromorphic cameras for battery-free sensing and visible light wireless communication of human interactions within smart environments. This includes integrating multiple modalities such as temperature, audio, touch, and various input devices.

3 Design Considerations

There are several key design requirements we sought to achieve with NeuroCamTag system.

- **D1. Self-powered, battery-and maintenance-free operation:** In a smart environment where sensing devices need to be pervasively deployed, the tags must operate for long periods without maintenance. The tags should be self-powered via energy harvesting and operate without batteries.
- **D2. Support rich wireless input:** The sensing devices should go beyond presence detection and user input. The tags should support a rich array of wireless interactions to include continuous input events, touch, temperature, pressure, voice based control, detect audio events or even multi-modal interactions to fit the environment and user needs.
- **D3. Support for adaptability and no device programming:** Lighting conditions in the built environment vary widely; therefore, the design of tags should support different lighting conditions by allowing modular

Fig. 3. Digital NeuroCamTag System Overview **A.** Battery-free wireless NeuroCamTag back and front view. **B.** Neuro-morphic camera receiving OOK modulated light signal from NeuroCamTag. **C.** Flow chart of the event processing pipeline decoding OOK message from sensor.

energy harvesting. Besides lighting, some tags should require no hardware programming, i.e., tags that operate by simple hardware components.

- **D4. Minimize components and cost:** The cost per sensing device (each NeuroCamTag) should be under \$10-\$20 to achieve meaningful deployment as environments outfitted with 100s of sensors are scalable at lower price points. To achieve lower costs, a single tag should have less than 15 components.

Taking into account these design goals, two tags were designed – *Digital NeuroCamTag* and *Analog NeuroCamTag*. These tags embody many of the design goals discussed above such as designing, developing, and validating our approach for interactive wireless sensors with neuromorphic cameras. While both analog and digital NeuroCamTags are self-powered (D1), support rich input sensing (D2), and wirelessly communicate with the camera at long distances using light from LEDs, there are some key differences. For instance, the digital NeuroCamTag uses an OOK modulation scheme and is much more power efficient and able to operate in a low lux environment (even 500 lux), as power is not needed for communicating a logic "0". On the other hand, our analog NeuroCamTag is "always on" and uses frequency modulation (FM) to communicate with the camera. In addition to power, the sensing and wireless communication in the analog NeuroCamTag is achieved by using a voltage-controlled oscillator (555 timer). The 555 timer is "capacitor/resistor programmable", requiring no software programming (D3) and are adaptable to varying light levels, as modular solar panels can be added or removed. Finally, both our tags consist of less than 15 components, lowering deployment costs (D4).

As outlined in our background section, neuromorphic cameras function asynchronously at the pixel level, enabling us to detect signals from multiple tags simultaneously during interactive events. Specifically, we use the EVK3HD neuromorphic camera, featuring 1 Mega Pixel from Prophessee [36], to process the visual signals emitted by our tags. While the camera we use is an evaluation kit camera, more recently, neuromorphic cameras that operate with STM32 microcontroller units (MCUs) are available for mass adoption [37].

4 Digital NeuroCamTag System Overview

In this section, we present a comprehensive overview of the digital NeuroCamTag System, as depicted in Figure 3. The system consists of two primary elements: the tag hardware and a software pipeline for processing input sensor data and detecting digital tags. These tags utilize ambient light for power; they detect user interaction, sense the environment, and transmit digital data wirelessly via light signals. The neuromorphic camera, positioned in a secluded, out-of-the-way area with a clear view of the tags, such as on the wall or up in the corner of a room, is able to constantly monitor the tag's activity. Upon receiving messages, our software algorithm first applies a filtering process that removes non-messages by the identified header. Following this, the decoding algorithm takes over, clustering messages from various digital tags to accurately extract and interpret the sensor data.

Fig. 4. Digital NeuroCamTag schematic

4.1 Hardware Design

Our digital NeuroCamTag hardware is broken down into energy harvesting, energy management, storage, sensing, computing with ultra-low-power MCU, and wireless communication. Figure 4 shows the layout of the circuit modules and the components chosen to optimize for self-powered operation.

Energy Harvesting: We utilize the IXOLAR SM141K06L solar panel to harvest ambient solar energy. This panel has dimensions of 1.654 inches X 0.906 inches X 0.083 inches and has a weight of 3.4 grams. It is designed to deliver an open-circuit voltage of 4.15 volts, though actual performance can fluctuate depending on the intensity of available light.

During our development phase, we evaluated a range of smaller solar panels, including models SM730K12L and KXOB25-05X3F, which differed in both size and photocurrent generation. Interactive user input necessitates both high-speed responsiveness due to constant sensing and continuous wireless communications capable of handling several messages per second, for example, for playing games like pong, using a battery-free wireless controller with knobs. The chosen solar panel meets our power requirements most effectively, offering an optimal balance of size, weight, power, and cost (SWAP-C) in relation to the predetermined message length (see §6.6).

Energy Management and Storage: The power output of solar panels fluctuates due to the varying lighting conditions (e.g. changing sunlight) of the environment, as well as user interaction, such as moving a battery-free input device. To provide stable voltage, we investigated several buck-boost devices such as LTC3808, BQ25570, etc., and finally chose AEM10941 due to its ultra-low cold start voltage of 380mV, startup current of 7.8μA and a quiescent current draw of <1μA(I_q). Finally, in addition to harvesting, we support capacitor based energy storage for battery-free operation. Our circuits support capacitor banks that can be soldered. We chose tantalum capacitors (ranging from 680μF to 0.4F) as they offer the lowest DC leakage properties and lowest equivalent series resistance (ESR). The choice of capacitor used depends on the bootup time vs storage capacity desired. In section §6.6, we detail trade-offs for choosing capacitor values.

MCU and Computation: When a sufficient voltage (3.3v) is achieved by energy harvesting, the AEM10941 chip onboard delivers power to our ultra-low-power 16-bit MCU MSP430G2553 that operates in five low power modes (LPM4, LPM3, LPM2, LPM1, LPM0). The lowest mode (LPM4) consumes as little as 80μA. We selected the MSP430 microcontroller due to its lower power operation, ease of use, the availability of open-source firmware libraries and toolchains, and its established presence within the embedded systems community. Our MCU switches between the different LPM modes between input sensing and wireless communication. For example, pressing a button triggers an interrupt from LPM4 (deep sleep), waking up the MCU into its active state for wireless communication and returning back to deep sleep mode (LPM4) to save power. Although LPM4 is the lowest, not

all interactions can operate in that mode due to the clock requirement for an ADC read. Therefore, only button press interactions switch between LPM4, whereas other interactions using ADC read, such as a temperature, moving a slider, rotating a knob, etc., operate between LPM3 and the active state.

Encoding Input Data and Wireless Communication: Our MCU employs a digital On-Off-keying (OOK) to transmit interactive events and sensor data by modulating LEDs wirelessly. We chose OOK for its power-saving advantage—when transmitting the binary sequence of "1" and "0", the LED remains on for '1' and off for the representation of '0', conserving power. Specifically, we calculate the LED's "on" time for a binary '1' by using formula 1 below:

$$\text{Half Bit On/Off Time} = \left(\frac{1}{BPS} \times \frac{1}{2} \right) \text{ms} \quad (1)$$

leading to significant energy savings, as no power is consumed during the '0' intervals. For instance, with a transmission rate of 1000 Bits Per Second (BPS), the LED lights up for just 500 microseconds for each '1' bit. As depicted in Figure 3, each digital NeuroCamTag message is comprised of 16 bits divided into four distinct segments: a 4-bit header for synchronization, a 4-bit identifier for tagging up to 16 unique tags, a single-bit parity for error reduction, and a 7-bit payload for data representation. The 7-bit payload was selected to accommodate a sufficient range of analog inputs (0-127), such as those from dials, sliders, or temperature sensors. For example, a temperature reading of 76° would be transmitted as its 7-bit binary counterpart (1001100). The 4-bit header is optimized for message synchronization with our camera's decoding algorithm (detailed in §4.1)

4.2 Software Pipeline

We now discuss our camera software for decoding wireless transmission from digital NeuroCamTags. Neuromorphic cameras capture encoded light signals as they can operate with high temporal resolution and detect changes within 100s of microseconds.

Filtering: Before we begin processing our signal, we employ the camera's spatial-temporal contrast filter (STC) to reduce noise. The STC filter works by analyzing camera input contrast across a scene over time and removes isolated events. This filter is particularly useful in scenarios where both the spatial relationships between objects and their changes over time are important.

Decoding: After filtering, when the first encoded message bit arrives, the decoding process starts. For instance, when a "1" bit arrives, which corresponds to an LED turned on, an event is logged as $e_1(p_1, t_1, x_1, y_1)$, where p_1 is the polarity of the event, t_1 is the timestamp, x_1, y_1 are the coordinates. Following the first event, when the LED turns off at timestamp t_2 , it generates a second event with a polarity of 0 at the same coordinate (see Figure 5).

- For each XY coordinate our algorithm creates a double-ended queue. As events arrive, they are continuously added to the appropriate double-ended queue by each coordinate. The events are also checked to ensure they do not exceed the expected message time threshold (Th_1). An event occurring after the threshold prompts the processing of all queues up to Th_1 at various coordinates, as shown in Figure 5C.
- While processing these queues during the second step, our camera software inserts "0's" in queues where significant time lapses follow a polarity shift from 0 to 1 or 1 to 1, as depicted in Figure 5 with long gray blocks.
- As a third step, the software converts queues into message candidates. During this step the parity bit is verified. Message candidates with incorrect parity are discarded.
- As the fourth and final step, the software gathers message candidates from various coordinates. These messages undergo a k-means clustering process as well as a majority voting process, where the most common message is selected as the output. The k-means algorithm is chosen for its computational efficiency, with the 'k' value determined by the number of tags present in the scene.

Fig. 6. Analog NeuroCamTag System Overview A. Battery-free wireless NeuroCamTag back and front view. B. Frequency modulated LED signal sent to camera C. Machine Learning, event processing pipeline that classifies activity.

Fig. 7. Analog NeuroCamTag Schematic

flexibility led to the creation of the analog NeuroCamTag, featuring break lines on our PCB (refer to Figure 6A), allowing for configurations with 2, 4, or 6 solar panels.

Power from solar panels goes to a Low-Dropout Regulator (LDO) TPS7A0333DBVR with ultra-low quiescent current (IQ) of 200nA, ensuring signal stability. Each LDO port connects to a 1000μF ceramic capacitor for a fixed 3.3-volt output.

555 timer oscillator and sensors: The output voltage from the Low Dropout (LDO) regulator is applied to an astable-multivibrator circuit using a 555 timer, which acts as a resistance-to-frequency converter. We utilized a CSS555 timer, an ultra-low power timer that consumes a minimal 5 μA at 1.2 V. This timer is part of a resistor-capacitor network consisting of resistors R1 and R2 and capacitor CT. The circuit generates oscillations at a specific carrier frequency and duty cycle, determined by the following relationship:

$$\text{Oscillation Frequency : } f = \frac{1.44}{((R1 + 2 \times R2) \times CT)} \quad (2)$$

$$\text{Duty Cycle: } D = \frac{(R1 + R2)}{(R1 + 2 \times R2)} \quad (3)$$

The carrier frequency and duty cycle are inversely proportional to the values of R1, R2, and CT. Lower values of these components yield higher frequencies and shorter duty cycles, whereas higher values result in lower frequencies and longer duty cycles. These component values (R1, R2, and CT) can be customized on our PCB (Figure 7), allowing the creation of new tags with distinct carrier frequencies or "IDs." This customization supports

the identification of multiple tags operating on a different carrier frequency. We tested $R_1=4M\Omega$, $R_2=470K\Omega$ and $C_T=1nF$ for a carrier frequency of 270Hz for the microphone tag.

In our circuit design (see Figure 7), the input signal to the Control Voltage (CV) pin of the timer modulates the output frequency and duty cycle. This modulation depends on the characteristics of the signal applied to the CV pin. Various sensors, such as microphones, light-dependent resistors, or pressure sensors, can be connected to this pin. They produce a frequency-modulated (FM) voltage signal at the output of the timer, which is then transmitted through an LED with a resistor, sending out the FM signal.

5.2 Software for Demodulating Analog NeuroCamTags

Similar to digital NeuroCamTag, an analog NeuroCamTag's LED blinks generate events with a polarity that indicate either ON or OFF states, triggered by changes in brightness from the tag's LED (Figure 6B). The tag's frequency modulation dictates the frequency of these events, correlating to the LED signal's frequency. Our camera records these events, capturing their timing and XY coordinates accurately. To extract the events, we use our camera API; specifically, we set a time buffer of 2ms; this ensures all events captured within the 2ms are passed to further processing blocks in the software pipeline.

Frequency Detection, Clustering and Filtering: To process the events along with their XY coordinates, we first convert each event that is timestamped into frequencies and cluster the frequencies to reduce redundancies using an implementation that is similar to FrequencyCam [33]. We then use a series of low-pass and high-pass filters to extract the signal of interest. For instance, our analog microphone NeuroCamTag uses 270 Hz carrier and uses a bandwidth from 250 Hz - 2KHz to modulate and send data; therefore, we filter out other frequencies (Figure 6C). However, if an environment has other sensors, such as resistive sensors (such as potentiometers, sliders, and light dependent resistors), they can occupy other parts of the available spectrum such as above 2KHz or below 250Hz, and their bandwidth is customizable depending on the resolution of the device desired.

5.3 Activity Recognition & Machine Learning

We use machine learning to classify activities based on the FM signal received from our analog NeuroCamTag. In particular, we used our analog battery-free microphone tag (Figures 1 and 7) to capture audio and send FM data wirelessly to our machine learning pipeline. Upon receiving and demodulating the FM signal, we extract features from a sliding window of 4000 data points and compute the time domain and frequency domain features. For spectral features, we used a 128 point Fast Fourier Transform (FFT) overlapping 50% from the signal data window. In addition, we used TSFEL [5], a feature extraction toolbox, to create spectral features (e.g. continuous wavelet transform, quantiles, binned entropy and etc.) In total, 41 features were fed into the machine learning model.

Figure 8 shows a series of different activities and their associated retrieved spectrum content. Note the variations in the duration, frequency bands, and amplitudes (intensity of color) for each of the activities.

For the classification of activities and user interactions, we use a random forest classifier although, other models e.g., boosted trees or dense networks are compatible with our analog NeuroCamTags).

We ran our random forest classifier using *Gridsearch* [32] to systematically determine the number of estimators and the random forest criterion (gini, entropy or log loss). Gridsearch determined 60 as the optimal number of estimators and 'gini' as the optimal criterion. These parameters were cross validated 5 fold by mean to determine the desired parameters.

Due to the variations in environmental conditions and end-use (i.e., applications), we expect that the system will require an initial calibration to train the activity classifier when first installed. Based on our preliminary studies, we have observed that this calibration can be accomplished in just a few minutes. However, if there is a change in the device type (e.g., replacing a microwave) that operates at a different frequency than the previous device, an additional calibration may be necessary.

Fig. 8. Activity spectrograms from microphone equipped, sound encoded, analog NeuroCamTag

6 Technical Evaluation

In this section, we detail a series of experimental evaluations of our combined hardware and software system across several key dimensions. These explorations focus on 1) Analyzing how range, transmission speed, and accuracy impact our sensing devices, 2) Measuring the accuracy of message transmission at different angles of attack in our tags, 3) Examining the density limitations of tag placement, 4) Investigating how background interactions influence accuracy, and 5) Conducting various tests to confirm the power efficiency of our sensors.

Our accuracy tests were conducted primarily on digital tags, which communicate via binary data (sequences of 1's and 0's). In contrast, analog tags emit a continuous signal. For these, we assessed the detectability of their modulated carrier frequencies under varying conditions, such as different distances.

Fig. 9. BPS and message accuracy

Fig. 10. BPS and bit accuracy rate

6.1 Experiment #1

Transmission Speed and Accuracy: To examine the range and transmission speed capabilities of our system, we implemented our digital NeuroCamTags encoding process, utilizing an LED device in the lab. We transmitted a 16-bit message (see §4.1) with varying identifiers corresponding to different transmission speeds: IDs of 0001, 0002, 0003, 0004 & 0005, representing speeds of 250, 1000, 2000, 3000, and 4000 BPS, respectively. Our testing involved moving our camera, equipped with decoding software, to distances of 10, 30, and 50 feet to gauge the decoding accuracy (see Figures 9 and 10). These distances were selected to mirror typical indoor room lengths. Our findings show a high message accuracy rate, exceeding 95% for all tested distances and speeds up to 3000 BPS. However, at 4000 BPS, accuracy notably decreased to below 75%, attributed to a hardware limitation in the camera's event processing capacity due to its readout architecture [33].

Table 1. Long Range Message and Bit Accuracy for through hole (THT) and surface mount (SMD) LED

Accuracy Type	LED Type	Distance	
		100 ft	200 ft
Message	SMD	95.0%	1.0%
	THT	90.0%	95.0%
Bit	SMD	97.4%	1.0%
	THT	89.8%	95.2%

Following our assessment of the message accuracy rate, we proceeded to analyze the bit accuracy rate. We attained a bit accuracy rate exceeding 97.6% at 3000 BPS, mirroring our message accuracy rate at this speed (Figure 10). However, as the transmission speed increased, the bit accuracy further declined. At 4000 BPS, we observed a bit accuracy rate of 62.7%, equivalent to approximately 10 bits received per 16 bits transmitted.

Analog Accuracy Experiment: As previously discussed, for analog tags, we conducted basic tests to detect modulated carrier frequencies of 300Hz, 1000Hz, and 2000Hz, the latter being the upper limit of our range. Our observations confirmed that these frequencies were successfully received using our demodulating software and demonstrated similar data throughput and range as the digital tag.

6.2 Experiment #2

Long Range and Accuracy Experiments: After establishing the maximum operating speed of our devices, we then tested their transmission range limits. We selected two extended distances of 100 feet and 200 feet for this purpose, with 200 feet being the maximum distance manageable in our indoor environment. At these distances, we implemented our message encoding and decoding software. We also explored the effect of LED type on transmission characteristics by comparing surface mount device (SMD) LEDs (part number IN-P32AT5UW) and through-hole (THT) LEDs.

The results were quite significant. At 100 feet, the THT LED sustained an impressive message accuracy rate of 90%. This is close to the SMD LED, whose accuracy was 95%. At 200 feet, the THT LED continued to maintain its accuracy level, but the SMD LED's accuracy fell to 1% (see Table 1). This difference in performance is primarily due to the higher microcandela (mcd) value of THT LED, which is 35,000 mcd, as opposed to the 1,000 mcd of the SMD LED. Because the neuromorphic camera operates by detecting changes in light's contrast, as the LEDs' distance from the camera increases, their mcd values diminish, leading to a decrease in contrast and, subsequently, impacting the transmission accuracy.

6.3 Experiment #3

Angle between Camera and Tag: Following our initial insights into the long-range capabilities of THT LEDs, we were motivated to explore further the dynamics of our system. We particularly focused on how the accuracy of message transmission interacts with the angle of attack and the type of LED. This led us to conduct another set of experiments that focus on these variables.

In these tests, we broadcast messages while varying the camera's position across different angles and distances. This setup allowed us to run our decoding pipeline under diverse conditions. The results, presented in Figure 11, reveal the accuracy of the message for both THT and SMD LEDs at distances of 10 and 50 feet and at angles from directly facing the sensor (0°) to nearly sideways (85°). In particular, at a 90° angle, neither type of LED was visible to the neuromorphic camera, and hence, 90° is not included in our analysis.

Fig. 11. Message accuracy (%) at different camera to LED viewing angles. THT: Through Hole LED (orange), SMD: Surface Mount Device (blue)

Fig. 12. Conceptual number of tags placed 1° apart on a 40' by 10' wall at 30' and 50' distance from camera.

Our tests revealed that the SMD LED delivered steady and reliable performance across all angles and distances tested. It was particularly effective at right angles of 0° and 90°, maintaining an accuracy rate of over 90%. This high level of consistency is likely due to the SMD LED's broad viewing angle of 120 degrees, which is significantly wider than the 15-degree viewing angle of the THT LED. Meanwhile, at a moderate angle of 45°, both the THT and SMD LEDs showed commendable performance, achieving accuracy rates of 99% and above.

6.4 Experiment #4

Contrast Effect on Accuracy: Neuromorphic cameras function by detecting changes in light contrast, prompting us to test two distinct background colors, white and black, to assess their impact on our tag design. In our experiment, we positioned an LED against either a solid white background (using copy paper) or a dark background (black poster board) and then transmitted our message. The camera was relocated to various distances (10 feet, 30 feet, and 50 feet) for testing, and we operated our message decoding software in different lighting conditions (with lights on and off). As Table 2 indicates, a dark black background provides consistently high recognition accuracy in indoor settings. Consequently, we suggest placing our tags against darker backgrounds for optimal performance.

6.5 Experiment #5

Distance Between Tags: To investigate the proximity limits for placing NeuroCamTags while maintaining high message accuracy, we positioned two tags at various angles relative to the camera. This setup allowed us to control their separation distances. We simultaneously broadcasted messages from these tags and then analyzed the decoded outputs. The separation distance between the tags was dictated by their angular distance in relation to the camera. For instance, at a 1° angle, as shown in Figure 12, the tags were 6.3 inches apart at 30 feet and 10.5 inches apart at 50 feet. We tested angles of 0.1°, 0.5°, and 1°, with the results detailed in Table 3, to identify the minimum viable distance between tags while maintaining high message accuracy.

Table 2. Message accuracy with different LED background contrast.

		Dark BG	White BG
10 Feet	Ambient light	99%	76%
	No light	99%	93%
30 Feet	Ambient light	97%	75%
	No light	100%	100%
50 Feet	Ambient light	99%	20%
	No light	100%	100%

Table 3. Message accuracy at different degree separation between tags.

	Degree of Separation		
Distance (ft)	0.1°	0.5°	1.0°
30	58.9%	80.7%	91.1%
50	58.9%	73.3%	85.6%

Our results demonstrated that message accuracy remained above 90% at 30 feet and exceeded 85% at 50 feet with a minimum angular separation of 1° between tags. These overall tag density measurements were calculated considering a 70° horizontal camera field of view. Additionally, Figure 12 illustrates the feasible tag density on a 10'x40' wall at distances of 30 and 50 feet, assuming a 1° angular separation between tags. Based on these findings, we estimate the capacity to place approximately 1400 tags on a 40-foot wall at 30 feet and around 578 tags at 50 feet.

Fig. 13. Power characteristics for NeuroCamTag A. Blink frequency for the digital tag in different light intensities. **B.** Minimum required light intensity for the analog tag in different solar panel configurations.

6.6 Experiment #6

As previously mentioned, to ensure interactivity (e.g., continuous user interaction through buttons, knobs, etc.), it's essential to transmit multiple messages per second. This not only minimizes errors but also maintains responsiveness. Given our message length of 16 bits and the Size, Weight, Power, and Cost (SWaP-C) limitations of our tags, we aimed to assess the power requirements for sensing and broadcasting multiple messages and determine the optimal transmission speed (BPS).

Operational Power Budget of Digital tag: As a first step, we measured the operational power needed for digital NeuroCamTags under various lux conditions. We measured this by using the Nordic Power Profiler Kit II as a power meter across the singular solar panel that charges our digital NeuroCamTag. The NeuroCamTag was made to run the *constant blink* program at 3000 BPS and would broadcast a message consisting of all 1's. The messages per second would be set so that the average power expended during operation would equal the average

Table 4. Energy expense to send a digital message at different BPS by various sensors.

BPS	Message Type			
	Constant Blink	Button Press	Read 1 ADC	Read 2 ADC
500	85.4 μ J	90.2 μ J	100.9 μ J	175.7 μ J
1000	49.4 μ J	53.9 μ J	55.3 μ J	102.4 μ J
2000	25.4 μ J	26.8 μ J	28.2 μ J	53.9 μ J
3000	13.6 μ J	13.8 μ J	15.9 μ J	30.1 μ J

Table 5. Cold Start Time In Different Lighting Environments

Capacitor	Cold Start Time		
	1500 LUX	1000 LUX	500 LUX
680 μ F 16V	47 s	1.8 min	3.9 min
2200 μ F 6.3V	2.5 min	6.8 min	12.3 min
4400 μ F 6.3V	4.8 min	12.0 min	22.8 min
0.047 F 5.5V	52.8 min	2.3 hr	4.5 hr
0.25 F 5.5V	3.6 hr	7.8 hr	15 hr
0.5 5.5VF	6.7 hr	18.3 hr	34 hr

power delivered by the solar panel, see Figure 13. Our results are as follows: at 1500 lux, digital tags operated with 360 μ W of power; at 1000 lux, they operated with 260 μ W of power; and at 500 lux, they operated with a mere 65 μ W of power.

Power per Sensing Type: We also performed a power analysis on four key input sensing methods expected to be supported by our digital NeuroCam tags. These methods include constant blinking (for purposes like ID and pose tracking), button presses (applicable in game controllers, reed switches, etc.), reading one ADC (suitable for temperature sensors, sliders, etc.), and reading two ADCs (for joysticks, operating dual sliders, etc.). As discussed in the section on MCU and Computation (see §4.1), it's noted that buttons function in a low-power mode 4 (LPM4), while other input types oscillate between low-power mode 3 (LPM3) and the active mode due to the requirement of an auxiliary clock for ADC Reads. We used the Nordic Power Profiler Kit II to measure energy consumption from MCU wakeup to sleep mode, capturing characteristics like ADC initiation, button press power, and BPS.

Our evaluation of the power cost per message for sensing and transmitting data is presented in Table 4. We experimented with varying message transmission rates, including 500 BPS, 1000 BPS, 2000 BPS, and 3000 BPS. We performed our analysis at 3000 BPS, which was the highest speed/accuracy that still allowed for high accuracy (see §6). The results indicate that a transmission speed of 3000 BPS was the most power-efficient across all input sensing types.

Lux vs Message Rate vs Sensing Type: After determining that 3000 BPS is the most energy-efficient transmission speed, our next task involved assessing the number of messages that digital tags could transmit under varying light conditions, ranging from 500 lux (low light) to 1500 lux (bright environments). We conducted this evaluation for our four input sensing methods: constant button, button press, 1ADC, and 2ADC. In this experiment, we adjusted the device's message rate until it reached a stable capacitor voltage in different lighting scenarios.

Our findings, as depicted in Figure 13A, indicate that at the lowest light level of 500 lux, we were able to detect and transmit multiple messages for both button presses and constant blinking. In moderate light conditions, ranging from 500 to 1000 lux, we successfully achieved the sensing and transmission of 3-5 messages per second for all input types except for 2ADC. In brighter settings, exceeding 1000 lux, the rate increased to 5-8 messages per second for all conditions, again except for 2ADC. These results align closely with the energy consumption per message type observed in our prior studies.

Operational Power Budget of Analog Tag: Additionally, we investigated the relationship between lighting conditions and the number of solar panels required for our analog tags to function optimally under various lighting scenarios. Table 13B presents the necessary configurations of solar panels corresponding to different lux levels. Given that the Analog tag operates in an "always on" mode, it has a higher power consumption. Presently,

our analog microphone tag includes an electric microphone with a gain amplifier, which consumes approximately 250 μ A, in addition to the 555 timer and the rest of the circuit components. Since our analog tags are adaptable to light conditions, their power budget is determined by the solar panels used. We characterize the power required to run these tags in different lux, as seen in Figure 13B.

Energy Storage vs Cold Start vs Capacity: Finally, we aimed to explore how the choice of energy storage (capacitors) impacts cold start times and tag energy life. We measured the time it took for the NeuroCamTag to start operating from a fully uncharged state, ranging from 0 to 3.9 volts on the storage capacitor, marking the beginning of the AEM10941's buck converter.

Our findings reveal that smaller capacitors have a quick 4-minute start-up time even under moderate lux (500) conditions, while larger capacitors have a longer cold start time. However, the trade-off is that smaller caps provide limited power during power failures compared to larger caps. This highlights the importance of selecting capacitors tailored to specific applications: smaller capacitors for intermittent systems like temperature probes or reed switches and larger ones for high-frequency interactions like joystick controllers or constant blinking ID tags.

7 Applications

We propose several interactive applications to demonstrate both digital and analog NeuroCamTags: 1) Sensors and Interactive Devices 2) Multi-user, Multi-tag applications, 3) Object Use Tracking in Smart Kitchen and 4) Object Use Tracking in Smart Workshop.

7.1 Sensors and Interactive Devices

Input Devices: Buttons, Sliders, Knobs and Joystick We developed a variety of rich input devices that incorporate NeuroCamTags. These include inputs such as pressing a button (as illustrated in Figure 14A), rotating a knob (Figure 14D), sliding a control (Figure 14C), and maneuvering joysticks across XY coordinates (Figure 14F). Each device utilizes the ultra-low-power MSP430 microcontroller unit (MCU) in the digital NeuroCamTag. This setup operates on an interrupt-driven basis, toggling between low-power states and an active mode. Specifically, the button-tagged device alternates between LPM4 and active state, whereas other input devices transition between LPM3 and active state. For input mechanisms like knobs and sliders, a basic resistive divider circuit is employed to monitor voltage changes through the ADC, broadcasting the voltage at a rate of 3000 BPS. This process occurs at an optimized frequency of 7 messages per second, ensuring the system remains sufficiently responsive for quick human interactions. In the case of the joystick input device, the tag is activated from LPM3 to first measure and transmit the ADC value for the 'x' axis, then pauses briefly for 5ms before measuring and transmitting the 'y' axis ADC value. This approach effectively tracks both axes of the joystick, maintaining a practical transmission rate of nearly 4 messages per second.

Interactive Sensors: We also provide a variety of interactive sensors designed to monitor smart environments. For example, in workshop or kitchen settings, our temperature sensors (illustrated in Figure 15) can detect temperature changes. Utilizing reed switches, we have developed an application for monitoring supply levels (Figure 16B). This system records each interaction, keeps track of inventory, and sends out wireless notifications when restocking is needed. Additionally, we have equipped smart moisture sensors (Figure 14B) to monitor the soil moisture around plants, using ADC readings from the MCU on our digital tags for wireless communication. The moisture data transmitted is compared against a pre-defined soil moisture threshold and alerts the user depending on needs. Additionally, we have incorporated pressure sensors in our tags, which are designed to log and monitor pressure as recorded by users.

Multiple User, Multi Tag Applications We demonstrate in Figure 16 our system's capability in managing interactions from multiple users concurrently engaged in a game of 'tic-tac-toe'. This interaction is facilitated

Fig. 14. Applications of digital NeuroCamTag A. Button Press B. Soil moisture C. Linear slider D. Rotary knob E. Pressure sensor F. Joystick controller

Fig. 15. Occlusion aware environment sensing A. Battery-free microphone modulated LED signal sent to neuromorphic camera in a workshop environment. B. Confusion matrix accuracy (%) for classes in the kitchen and the workshop.

using two analog NeuroCamTags, each set to a unique carrier frequency that corresponds to specific display colors. Our system decodes these frequencies along with their locations to map them on the display, enabling each player to simultaneously draw on the screen in their distinctive colors.

Figure 2B depicts a pong game with two users employing the digital NeuroCamTag model pictured in 14D. Here, each game controller incorporates a tag assigned with a distinct "ID." This unique identification allows the system to accurately distinguish and process the signals emitted from the rotary sensors in each controller.

7.2 Smart Environments - Kitchen & Workshop

Using our battery-free analog and digital NeuroCamTags, we have created a smart kitchen and workshop environment, as illustrated in Figure 15. In both the kitchen and workshop, we deployed temperature sensors, reed switches, and a microphone tag.

Sensors We employed a temperature sensor on the oven (Figure 1) to monitor its temperature in the kitchen and on a hot glue gun (Figure 2) in the workshop. Reed switches were utilized to track the usage of kitchen drawers (1). Additionally, our analog microphone tag was deployed in both environments to monitor and predict activities using the previously described machine learning (ML) pipeline. The system enables us to track and predict the usage of various objects in both the workshop and the kitchen.

Activity Recognition The analog NeuroCamTag system was deployed for recording data from both the kitchen and the workshop. Notice in our workshop environment (Figure 15), that even though the user activity is occluded, our system can still pick up audio data. We collected data for eleven activities: Microwave, Faucet, Blender, Mixer, Vacuum, Blower, CNC, Drill, Hammer, Hot Air Gun, and Silence. During raw data collection by the Neuromorphic Camera, only one object was active at a time. Each activity was recorded twice, with a duration of 120 seconds for each recording. The machine learning model was trained on data collected over three different days, with each day's sessions having distinct lighting conditions to ensure the model's robustness.

The NeuroCamTag machine learning model evaluation utilized a leave-one-out cross-validation method by collecting a separate, never-used dataset. The analog NeuroCamTag system demonstrated an average classification accuracy of 96.3% across various objects in specific locations and diverse ambient light conditions. Notably, the false positive rate remained low at 1.3%. Specific details regarding classification rates for each object are detailed in the confusion matrix (Figure 15). For example, the misclassification of a "hot gun" as a "faucet" exhibited a false positive rate of 11%. Similarly, the misclassification of a "drill" as a "blower" exhibited a false positive rate of 3.7%. These observations shed light on the system's behavior in specific recognition scenarios, indicating areas for potential refinement and further investigation.

Fig. 16. Multi-user interactive controls demo A. Analog NeuroCamTag playing Tic-Tac-Toe B. Digital NeuroCamTag reed switch monitoring cabinet access

7.3 Long-Term Deployment Study: Kitchen

7.3.1 Procedure. We used three digital NeuroCamTags in a kitchen setting from Figure 1, featuring two drawer monitoring tags (reed switch) and one toaster monitoring tag (temperature sensing). The location mimicked actual real-world deployment and NeuroCamTags were used in an everyday setting. The lowest lux measured throughout the experiment was 746 lux. Our system was deployed for 144 hours, and one experimenter visited it several times each day. Each of the digital tags was configured to broadcast every second at 3000 bps. During each visit, one or multiple tasks were performed, such as opening a drawer and/or turning on the toaster to either the 'toast' setting or the 'warm' setting. The task, time, and duration were recorded manually to establish ground truth interactions. Additionally, the start temperature and peak temperature were recorded using an AMES infrared thermometer.

7.3.2 Results. Figure 17 shows each device's status for the 6-day period. Over the 6-day period, over 2,000,000 data points were collected. The 36 ground truth operations were compared to the recorded data, 100% of actions were detected. Additionally, as seen in Figure 17, the toaster temperature monitor recorded both the temperature of the toaster during use and ambient temperatures when it was not in use. Also, while there were only 36 actions, the drawer sensor can detect how long the drawer was open (from close to open to close).

Fig. 17. Multiple event distribution over time of three NeuroCamTags deployed over a 6-day period. The events show the continuous operating nature of the tags sensing activities, which include using a toaster oven and opening/closing drawers.

8 Discussion

In this section, we compare our work and discuss the advantages over existing work in two key areas: visible light communication (VLC) based sensing systems and battery-free RF sensing.

8.1 Visible Light Communication and Sensing

In the field of visible light communication (VLC) based sensing systems, a wide array of research has significantly advanced the technology. Schmid et al. [44] initially developed an LED to LED VLC system, achieving data transmission over 2 meters at 800 b/s utilizing 289 mW, and later enhanced this with an IoT VLC system [45] using PWM ON-OFF Keying for up to 400 b/s transmission. Additional work in low-power communication technologies includes Xu et al. [57], who developed Passive VLC in 2017, noting a power consumption of 150 μ W and achieving a range of 4.5 meters. Additionally, the RetroVLC system, with a power consumption of 90 μ W, demonstrated effective communication over distances of up to 2.4 meters [24]. Wu et al. [55] introduced RetroTurbo, which reached 7.5 meters and consumed 0.8 mW transmitting up to 8 kbps. Xu et al. [56] built RetroMUMIMO and investigated concurrency in visible light backscatter communications (VLBC) to reach 3.75 meters using 0.2 mW emphasizing reflective architectures. LightAnchors [1], closely aligned with our research, utilized advancements in slow-motion cameras, such as the iPhone 7's 240 fps feature, to detect point light LEDs in a scene. Though effective, LightAnchors relied on energy-intensive traditional RGB cameras that require constant operation for cue detection. In contrast, our works novel neuromorphic cameras, which are highly energy-efficient (about 1mW) and capable of an impressive 4000 Hz (4000 FPS) data capture rate per pixel. This enables the simultaneous capture of multiple point light LED sources at high frame rates.

Moreover, our study showcases the capability for long-range battery-free sensing of user interactions (Figure 18), operating at a mere 65 μ W, even in low-light (500 lux) conditions, as detailed in the section on the operational power of the digital tag (Section §6.6).

8.2 Battery-free RF Interaction sensing

Battery-free wireless interactive sensing systems come in two categories: those that require instrumentation of objects with tags such as RFID [42] and those that take advantage of wireless signals around us such as Wi-fi, mmWave, etc not requiring labels and use RF reflection from human/object movement to detect interaction. We now go over a brief overview of these works.

Fig. 18. Distance and power comparison of recent Visible Light Communication (VLC) technology [1, 24, 28, 55–57]

8.2.1 Tag-based RF Sensing approaches: To provide battery-free RF sensing, the tagging based approach relies on designing tags that harvest ambient energy from the environment to wirelessly communicate about interaction. There is a need to balance energy harvesting from environmental or human interactions with power efficiency, functionality, circuit complexity, and form factor. Amongst tag-based RF Sensing approaches is Wang’s LightSign [53], which combines VLC with RFID adding a photodiode to an RFID circuit to enhance tag localization, but are range limited due to light power requirement.

The first battery-free wireless sensors are rooted in RFID tags like WISP [42, 51] and Moo [31]. They featured programmable tags with onboard sensors wirelessly communicating via radio frequency backscatter. This led to the development of a hybrid analog-digital modulation scheme using WISP [48] for transmitting acoustic data. RFID based sensor advancements were furthered in PaperID [21], RapID [47], ID sense [23], LiveTag [15], and RF Bandid [39], extending to touch interactions and multi-touchpoint detection. Similar to RFID backscatter mechanisms, other Wifi-based backscatter tags [60], mmWave based backscatter tags [27] have also been proposed for on-body sensors and environmental monitoring, respectively.

Finally, RF tags have also focused on purely analog communication [3, 28, 40, 61] due to their simplicity and power efficiency. For example, Ranganathan et al. [39] demonstrated RFBandid operating at 160 μW with a range of 9 meters. Although all these advancements are notable, most of the aforementioned RF tag based sensing technologies have a limited range of ~12m

Recent advances such as Lorea [52], Lora Backscatter [49] tags have extended these ranges to several hundred meters. For an in-depth analysis of the relationship between range and input power at the transmitter, we direct the readers to the work of Ranganathan et al [40] (see Figure 9 in that paper).

Furthermore, there is an array of non-backscatter communication techniques, i.e., active communication, in the realm of battery-free sensors that offer extended range but at the cost of increased energy. This category encompasses straightforward sense-and-transmit sensors powered by ambient energy, these include systems that use, energy-harvesting, and commodity radio communication technologies such as low-power BLE.

For instance, Fraternali et al. introduced Pible in 2018, harnessing BLE Advertising with a power consumption of 648 μW [11]. Jeon's luXbeacon, operating on the nRF51822 platform, offers a power-efficient solution with an estimated range of approximately 100 meters [20]. Similarly, Saoda et al. developed Herald in 2019, boasting a power consumption of 200 μW and a similar range estimation [43]. Yang et al. [59] created Minikers, tags that harvest kinetic energy from human interaction to actuate devices such as opening blinds and communicate via BLE.

8.2.2 Tag-free RF Sensing approaches: Unlike NeuroCamTag, which uses a physical tag, tag-free sensing exists and uses RF to communicate, locate and identify gestures, poses and activities. Several RF-based systems leverage WiFi for activity recognition [25, 38, 41] and some use mmWave [58, 62] for activity recognition.

8.2.3 Comparison to existing RF sensing approaches: Our work has several advantages over RF-based approach in general. First, NeuroCamTags is based on visible light and thus completely immune to the interference from RF spectrum, which is already crowded with “default” LAN and WPAN technologies such as WiFi, BLE. Second, because of the backscattering nature, some of the aforementioned RF-based systems tend to expose their transmissions to a wide surrounding area, leaving a good chance for side readers to overhear the information being transmitted. In contrast, NeuroCamTag relies on VLC, where signals are confined within a physical space and cannot penetrate walls, providing better security and privacy compared to RF signals. Through the use of highly directional LEDs, we can further constrain the uplink transmission to stick along the tag-reader path. Overall, NeuroCamTag has good security properties, while other RF systems have to enhance their security with extra efforts (padding, delaying packets, or injecting dummy traffic) [6]. Additionally, by leveraging physicality of the NeuroCamTags can provide agency to users to control privacy. For instance, using tape to cover the LED makes for a more cost effective means of privacy [9]. Finally, VLC systems do not cause electromagnetic interference like RF systems, making them suitable for use in sensitive environments like hospitals, etc. where sensors need to be deployed and non-interference to RF medical devices is crucial. Similarly, in environments that produce high EMI, like factories with heavy machinery, NeuroCamTags could ensure reliable machine-to-machine sensing and communication.

9 Limitations & Future Work

Power: Further power optimization could be a future goal. For instance, our current implementation of the analog tag is not optimized to run in the ultra-low-power mode of the CSS555 timer. The timer can run under 5 μA by reprogramming the EEPROM. Furthermore, LDOs such as the TI TPS7A0328DBVR, which operate at lower voltage levels, are available to further reduce the power budget for analog tags. Likewise, the power consumption for operating microphones can be optimized through the utilization of an ICS-40310 MEMS microphone, capable of running on a 1V supply and consuming as little as 16 μA of current, all while delivering a 64dB SNR. Similarly, other ultra-low power MCUs like the Apollo4 [50] could be explored for Digital NeuroCamTags.

Additional Energy Harvesting Techniques: The current implementation of our tags operates solely on ambient solar power. However, future iterations of NeuroCamTags could utilize alternative sources such as harvested piezoelectric, thermal, motion, etc. Prior research [26, 63] has explored various sources that are opportunistically available in the built environment.

Modulation and Error Correction techniques: Additional modulation techniques such as phase shift keying (PSK) could be explored and might improve the ability of our system to pick up event transmissions even faster. However, they would require additional changes to the camera sensor's hardware and software. Finally, lightweight error correction techniques such as hamming codes could be explored by increasing the parity bits.

Line of Sight Operation: Due to the directional nature of light, NeuroCamTags inherently benefit from enhanced security, such as being resistant to eavesdropping. However, it also faces a fundamental limitation, shared by all visible sensing and communication systems, in that it cannot function in non-line-of-sight scenarios.

Direct Edge Sensing and Multi-class predictions

As we continue to develop NeuroCamTags, effectively managing complex computational tasks becomes essential away from the edge and in centralized processing environments. Our current setup, which includes the analog audio tag, does not utilize on-device machine learning; instead, it relies on centralized processing near the camera. This approach allows us to leverage algorithms that require greater computational power than edge devices typically provide.

A significant opportunity for future enhancement is the ability to detect multiple active devices simultaneously—a challenge often referred to as polymorphic multi-classification [30]. While our system currently employs classical machine learning techniques for single-class detection, expanding to use dense neural networks (DNNs) for multi-classification tasks could be possible because of the computational power available away from the edge. This progression would enable more sophisticated and responsive interactions in smart environments, taking full advantage of the computational capabilities available near the camera.

10 Conclusion

With our work on NeuroCamTags, we demonstrate a novel approach to enable battery-free, long-range wireless sensing utilizing neuromorphic cameras. We demonstrate through technical evaluations the robustness of our approach with respect to sensing at long distances as much as 200 feet across a variety of lighting conditions, including low light (500 lux) and across wide placements in an environment. We demonstrate a range of rich interactive sensing opportunities with NeuroCamTags, including battery-free input devices such as buttons, sliders, and knobs, with multiple multi-user application devices. Furthermore, we demonstrate the ability of the NeuroCamTag system to monitor using up to 11 objects in two smart environments (a kitchen and a workshop) with a high activity recognition accuracy of 96.3%. Our techniques enable a rich interaction application space for HCI researchers with a focus on creating battery-free and eco-friendly intelligent environments.

Acknowledgments

We thank all the reviewers for their insightful feedback on improving this paper. We also appreciate the valuable suggestions, feedback, and initial efforts from Hasibul Alam, Christian Tongate, and Adithya Sastry.
