This Dissertation is brought to you for free and open access by the Graduate School at Trace: Tennessee Research and Creative Exchange. It has been accepted for inclusion in Doctoral Dissertations by an authorized administrator of Trace: Tennessee Research and Creative Exchange. For more information, please contact trace@utk.edu.
To the Graduate Council:

I am submitting herewith a dissertation written by Douglas Allen Sain entitled "Pre Clovis at Topper (38AL23): Evaluating the Role of Human versus Natural Agency in the Formation of Lithic Deposits from a Pleistocene Terrace in the American Southeast." I have examined the final electronic copy of this dissertation for form and content and recommend that it be accepted in partial fulfillment of the requirements for the degree of Doctor of Philosophy, with a major in Anthropology.

David G. Anderson, Major Professor

We have read this dissertation and recommend its acceptance:
Gerald Schroedl, Kandace Hollenbach, Boyce Driskell, Sally Horn

Accepted for the Council:

Dixie L. Thompson

Vice Provost and Dean of the Graduate School

(Original signatures are on file with official student records.)
Pre Clovis at Topper (38AL23): Evaluating the Role of Human versus Natural Agency in the Formation of Lithic Deposits from a Pleistocene Terrace in the American Southeast

A Dissertation Presented for the

Doctor of Philosophy

Degree

The University of Tennessee, Knoxville

Douglas Allen Sain

August 2015
ACKNOWLEDGEMENTS

This dissertation would not have been possible without the help and support of many individuals. I must offer my sincere appreciation and gratitude to my advisor, mentor, and committee chair, David G. Anderson, whose advice, friendship and recommendations helped make this dissertation possible. Through David’s knowledge and guidance, I have gained much insight into prehistoric archaeology and his helpful suggestions over the course of my research have greatly benefited this project. I would also like to thank the members of my dissertation committee for their time, patience, efforts, and editorial advice: Boyce Driskell, Gerald Schroedl, Kandace Hollenbach, and Sally Horn. Boyce Driskell provided me with the use of the microscope and also the lab space necessary to complete the microwear analysis. Boyce’s knowledge of chipped stone tools and lithic analysis helped me formulate my research design. Sally Horn offered space and equipment necessary to conduct pollen analysis which was instrumental in reconstructing the paleoenvironmental record at Topper. Gerald Schroedl and Kandi Hollenbach provided editorial advice which provided greater substance to the final product. Their insightful comments and constructive criticism helped me focus my ideas throughout this research.

A big thanks goes to Dr. Albert C. Goodyear of the South Carolina Institute of Archaeology and Anthropology for providing me with access to the archaeological collections, site level forms, and field notes housed at the South Carolina Institute of Archaeology and Anthropology (SCIAA). Al’s suggestions greatly helped me develop my research ideas and he was also instrumental in assisting me with the production of the site and excavation chapter of this dissertation. Moreover, Al’s guidance, friendship, and direction, helped me acquire the courage to tackle such a massive undertaking and ultimately see it through to completion.
Through countless conversations with Al I was able to stay on track and not lose sight of my goals.

I would also like to thank the faculty and staff of the Anthropology department at the University of Tennessee for providing me with the additional space necessary to conduct and complete my analysis. The lab space and equipment that was provided facilitated the analytic process. I am also grateful to the Anthropology department, graduate school and GSS through support of a number of research and travel awards. Without the assistance of these grants, the completion of this dissertation would not have been completed in a timely manner. On several occasions, I have intruded upon multiple individuals to ask questions about GIS and statistical methods that I was not entirely familiar with, but thought might be useful. To this regard, I would like to extend thanks to Greg March and Steven Yerka for their assistance with such procedures. Greg provided me with the software necessary to conduct many of the spatial and statistical analyses for this project, and Steven took time out of his schedule to discuss the inner workings of Arc GIS. The efforts of these individuals are much appreciated.

I would like to acknowledge and thank my friends and colleagues at the University of Tennessee. They deserve special consideration for their willingness to assist, discuss and help me hash out ideas about my research. To Thaddeus Bissett, Stephen Carmody, Alex Craib, Megan Dennison, David Echevery, Sean Cary Gunter, Michelle Hammond, Erik Johanson, Adrianne Kembel, Megan King, Robert Lassen, Martin Walker, and Sarah Walters, your friendship is greatly appreciated and you all have helped me maintain sanity over the course of my research. Countless discussions with these individuals and subsequent suggestions were instrumental in the inspiration and development of my research. I would also like express my gratitude to Laurie Wyatt for taking her time to assist with departmental matters.
I thank the many staff, visiting lecturers, and volunteers that frequent the Topper Site and Southeastern Paleoamerican Survey for offering their intellectual input: In particular I thank my colleagues D. Shane Miller, Ashley Smallwood, Derek Anderson, Joe Gingrich, Jessica Phillips, Dennis Stanford, William Andrefsky, Kara Bridgeman Sweeney, Chris Moore, Randy Daniel, Andy Hemmings, Beth Bell, Jesse Tune, Joe Wilkinson, and Tom Pertierra. The help and insight of numerous Topper volunteers was also beneficial to the final product. Bill Covington, Jean Guilleaux ,Carol Reed, Paula Zitzelberger, Carey Geiger, Bob Cole, Kenn Steffy and many others dedicated their time and labor in assisting with excavation. Without the assistance of these and many other avocational Archaeologists and volunteers who helped with the yearly excavations at Topper, the data necessary to conduct and carry out my research could not have been available.

I would like to thank the many students at the University of Tennessee who assisted with artifact analysis and sorting in the lab. Stephanie Palaskas, John Pontiff , Ledominique Ridley, Kristina Sarten, Nicolette Scarfo, Celina Scruggs, – your help with artifact sorting and data recording in the lab was a vital part of this project, without which the completion of this dissertation would not have been possible.

Most importantly, none of this would have been possible without the love and support of my family .My parents and brothers have been a constant source of strength and have believed in me over the years. To them, I owe heart–felt thanks and gratitude. To the people I have listed above, and many others that I am sure to have missed, I am utmost grateful.
ABSTRACT

This dissertation provides a detailed analysis of the lithic materials from the presumed pre Clovis deposits at the Topper Site (38AL23), a Paleoindian quarry and stone tool manufacture site in Allendale County South Carolina, U.S.A. Prior research at Topper identified flakes and possible chipped stone tools from Pleistocene-aged sediments that predate Clovis, traditionally considered the earliest culture complex in the region. The goal of this study is to document the nature of the pre Clovis assemblage at Topper, and to explore possible ways it may have formed. Did human or natural processes play a role in the production of a bend break assemblage, and does the occurrence of flakes from the lower deposits reflect a legitimate pre Clovis occupation, or the product of displacement from the overlying sediments? Lithic items from a sample of mapped and screened materials were examined for this study. Technological and experimental analyses were conducted to differentiate between the attributes of human and natural agency.

The Clovis and pre Clovis assemblages are composed of different frequencies of debitage and tool categories and reflect dissimilar reductive technologies. Technological attributes consistent with human agency were identified on bend breaks. This evidence supports the proposition that bend breaks were used as expedient tools and therefore served a functional role for pre Clovis occupants at Topper.

The experimental analyses demonstrate that chert is susceptible to fracture when exposed to prolonged episodes of weathering. Natural processes can result in the formation of detachments that resemble the morphological properties of flakes and bend breaks but lack the technological attributes that are characteristic of human lithic manufacture. A spatial analysis found that postdepositional processes have had minimal influence on the stratigraphic integrity
of the pre Clovis deposits and the occurrence of flake tools from these contexts is not the product of downward migration of artifacts from the Clovis deposits. The results of this study present a unique record of the behaviors of Late Pleistocene hunter-gatherers of the American Southeast. Support for the presence of human cultures that predate Clovis in North America should consider the inclusion of a broad range of reductive technologies.

CHAPTER I

INTRODUCTION

Between 1983 and 2012, archaeological excavations conducted at the Topper Site (38Al23) in Allendale County, South Carolina, revealed a substantial assemblage of chipped stone tools and the byproducts of stone tool production. The Topper Site (Figure 1–1) is a prehistoric quarry, having buried archaeological deposits that span the entire known cultural sequence from the region. The site is located near multiple resources that would have provided an excellent location for prehistoric peoples to establish base camps while procuring chert for the manufacture of stone tools.

The chipped stone assemblage recovered from Topper derives from stratified alluvial contexts and includes dense Clovis deposits, the earliest widely accepted culture complex to have inhabited North America approximately 13,250–12,850 cal yr B.P. (Waters and Stafford 2007). Excavations into deeper sediments at the site, below the Clovis deposits, revealed an assemblage of lithic items that some claim is evidence of an earlier pre Clovis occupation (Goodyear 2005). This older "pre Clovis assemblage" has been characterized as a smashed core and microlithic industry technologically distinct from traditional biface or unifacial flaking, although there are also flakes in the deposits from these more traditional lithic reduction strategies whose origin and presence must also be noted and explained (Goodyear 2005).

The Topper pre Clovis assemblage is thought to have been formed from a bipolar lithic reductive technology. Bipolar technologies produce lithic detachments through the application of compressive or wedging force to a core. Bipolar flaking is accomplished by placing the nucleus of stone to be struck, referred to as the objective piece, on a larger stone object referred to as an anvil, and subsequently striking the nucleus from above (Cotterell and Kamminga 1987). Lithic
Figure 1–1
Topographic map showing location of the Topper Site (38AL23). Allendale County, South Carolina. (Image courtesy of ESRI).
detachments formed by compression or bending fracture initiation in this way create multiple sharp edges that could serve as multifunctional “bend break” tools, and can therefore be distinguished from flakes produced using hertzian fracture initiation. Hertzian fracture occurs when a hard round percussor is struck perpendicular into the surface of a brittle solid (Cotterell and Kamminga 1987:685). Research has shown that the material byproducts of bipolar technologies often result in angular shatter, and assemblages with high percentages of such byproducts are often considered to be the result of non-human processes (Andrefsky 2013). Therefore, the designation of Topper as a legitimate pre Clovis site is problematic since the role of human agency in the creation of this lithic assemblage is in doubt. Although radiocarbon and Optically Stimulated Luminescence (OSL) dating of the sediments containing this assemblage have confirmed that they predate Clovis (Waters et al. 2009), the specific agent(s) of production and deposition, whether by natural or human processes, remains to be thoroughly tested.

An initial technological analysis of the lithic materials recovered from six 1m x 1m column test units at Topper demonstrated the presence of cultural artifacts in contexts that underlie the Clovis–bearing deposits at the site (King 2012). Using Sullivan and Rozen’s (1985) Interpretation Free Model (IFM) of flake analysis, King (2012) was able to show that conchoidal flakes typically produced by biface technologies do occur in the pre Clovis components at Topper. The concept of the IFM is that the interpretation of debitage variability is improved by the formation of analytic categories that describe assemblages as a whole as opposed to individual artifacts, and therefore does not depend on making technological inferences at the artifact level (Sullivan and Rozen 1985:755). King performed statistical analyses to test whether or not the presumed pre Clovis assemblage was similar in form to the attributes of known cultural assemblages. King found no significant difference between the physical attributes of
lithic debitage recovered from the Archaic and Clovis deposits, and the lithic items recovered from the reported pre Clovis aged deposits below (King 2012). She developed two alternative hypotheses to account for these results. Either the extant distribution of pre Clovis conchoidal flakes does reflect a legitimate human occupation at the site, or these flakes are the result of postdepositional disturbances resulting from downward movement by bioturbation or fluvial processes (King 2012).

The analytic framework King (2012) used to identify flakes was designed to distinguish between the attributes of conchoidal flakes and non-flake debitage. Her goal was to look for obviously flaked artifacts and to evaluate their distribution relative to the known cultural deposits. As such, the analyses were not developed to account for attributes that may form because of bipolar, bending, or compression initiation and therefore the approach does not consider the potential variability inherent in alternative strategies of chipped stone tool production. Because it is possible that flakes resulting from bipolar production may be present among the pre Clovis deposits at Topper, any research strategy geared toward establishing the legitimacy of the pre Clovis deposits at the site must incorporate a methodology that can account for the full realm of chipped stone technologies as well as the attributes that distinguish between them. Here I will examine the lithic contents of the Topper Site in detail, with the ultimate goal of determining the process(es) responsible for the production or deposition of the lithic items from the pre Clovis deposits at the site.

While excavations into the Topper hillside Clovis deposits have been partially documented (Miller 2010; Smallwood 2010, 2012; Sain 2011), much less has been published on the results of the Topper terrace excavations. Goodyear provided yearly accounts that summarize the fieldwork at the site through popular South Carolina Institute of Archaeology and
Anthropology (SCIAA) Legacy articles. Derek T. Anderson documented work conducted in the Early Archaic and Clovis 4m x 4m excavation block as an ongoing project to record artifact refits and examine the spatial integrity of the deposits in this part of the site (D. T. Anderson 2011). Sarah Walters conducted paleoethnobotanical work on materials recovered from the Holocene and Late Pleistocene deposits of the Topper hillside and colluvial terrace deposits. This work was documented in a number of poster and conference presentations and resulted in the first Clovis date at the site from an assay on a charred piece of wood (10,958 +/- 65 14C yr B.P.) (AA100294) (or 12,841 +/-62 cal yr B.P.).

The geoarchaeological work at Topper conducted by Waters et al. (2009) has provided the most rigorous analysis to date on the geostratigraphy and geoarchaeological components of the site. The pre Clovis component of the Topper Site has been incompletely documented at present. One MA thesis (King 2012), short popular articles, and several online publications have been produced giving an overview of the assemblage. A book chapter provides a brief technical summary of the work, in general terms (Goodyear 2005). The chapter highlights the major pre Clovis discoveries in the southeastern U.S. and includes two pages of discussion of Topper, making reference to the unusual microlithic artifacts associated with a bipolar core technology as well as an emphasis on choppers (Goodyear 2005).

The MA thesis research by King (2012) is to date the most comprehensive investigation on the pre Clovis component at Topper. Apart from the thesis and the short reports, little else has been published regarding the pre Clovis component at Topper. This stems largely from the general absence of a large scale, yet systematic analysis conducted on the materials recovered from the hypothesized pre Clovis lithic deposits. A recent analysis conducted by Goodyear and Wilkinson (n.d.) to examine the attributes of a sample of bend breaks recovered from the pre
Clovis deposits yielded some preliminary results regarding these possible artifact forms. Most items examined were tertiary, had between two and four snapped or broken edges that formed isosceles angles, and had one or fewer utilized edges. Moreover these items typically lack thermal alteration, and of 322 total snap angles examined, 17% exhibit utilization. The current study examined a larger sample of bend breaks from Topper in greater detail to determine how they were formed (Chapter 7).

Although prior archaeological studies of the Topper assemblage demonstrated the presence of humanly produced artifacts from the pre Clovis deposits, these findings did not establish whether the debitage in the deeper levels could have been produced by people living at the site prior to arrival of Clovis populations. To date, no formal investigation at Topper has examined the potential depositional processes that could have been responsible for the introduction of lithic materials into older deposits nor have analyses been conducted to examine the role of human agency in the production of the chipped stone artifacts that have been claimed to represent a pre Clovis assemblage at the site. This study attempts to resolve these issues.

**Research Objectives**

The primary objectives of my research are: (1) to establish the origin of lithic items that have previously been identified as flakes from the pre Clovis deposits at the Topper Site, and (2) to test the role of human agency in the production of the materials preliminarily identified as bend break flakes from the site. With regard to point (1), natural processes including weathering, eluvial downdrift, bioturbation, and fluvial transport can redeposit flakes from original contexts of deposition, or can form flakes that appear cultural. In addition to the flakes King reported from pre Clovis contexts, Goodyear also noted the presence of a possible tool assemblage consisting of chert cores, choppers, and scrapers in contexts associated with the pre Clovis
microlithic assemblage (Goodyear 2005). Is the pre Clovis flake assemblage related to the production of these tools, or have the flakes been redeposited from overlying cultural Archaic or Clovis contexts? Are the reported tools a legitimate cultural assemblage, or have they been formed by natural processes?

With regard to point (2), is there demonstrable evidence for bend break flakes among the contents of the Topper pre Clovis deposits, and were such flakes the product of bipolar production? In other words, is the bipolar and bend fracture lithic technology at Topper the result of intentional human lithic reductive episodes, conducted for the purpose of the production of stone tools, or are the materials found in the pre Clovis deposits created by other geological or natural means such as mechanical weathering, sediment consolidation, or freeze thaw processes?

To address these questions I undertook a thorough examination of the lithic attributes of a large sample of items recovered from the pre Clovis assemblage at Topper was undertaken. Of 392 m² of excavation from the Floodplain portion of the site where the pre Clovis deposits are located, materials from 52 m² of Holocene and Pleistocene – age Sands and 12 m² of materials from a Pleistocene-age Terrace were analyzed. These materials comprise 140 m³ of excavated sediments. Of these units, 54 m³ of Holocene and Clovis deposits were examined, only 33 m³ of which have data on screened materials. In addition to these deposits, 44 m³ of pre Clovis Pleistocene-age sands, and 42 m³ of the underlying Pleistocene-aged Terrace deposits were also examined.

Table 1–1 presents the yearly distribution in terms of square meters of excavated units opened on the Alluvial terrace at the Topper Site, whereas Table 1–2 presents the total extent of excavated materials in cubic meters that comprise the study sample. Table 1–3 presents the analysis sample highlighting the number of mapped and screen items recovered from each
Table 1–1
Square meters of excavated units opened on terrace by year at the Topper Site (38AL23, Allendale County, South Carolina). Screen artifacts includes those recovered from the screen, identified as specific artifacts in the field, and recorded in the level records, yet do not have any three dimensional provenience information.

provenience unit examined. Accordingly, 74,370 lithic items were recovered, identified, and classified as part of this project and include over 11,000 complete flakes (nearly 6,500 of which derive from pre Clovis contexts) as well as nearly 300 bend breaks and 653 chipped stone tools and production implements from pre Clovis deposits (Tables 1–4 and 1–5). Table 1–6 presents the attributes of the sample of bend breaks from the Goodyear and Wilkinson study.

The assemblage was evaluated with regard to the site stratigraphy to establish whether postdepositional processes have created or altered the lithic deposits. In addition to these analyses, an experimental program was developed to determine the visible effects of mechanical weathering on chert cobbles. Mechanical weathering influences such as air temperature, moisture level, and water temperature were replicated in the lab on a sample of Allendale chert cobbles. The goal of this procedure was to determine if chert exposed to prolonged and cyclic weathering processes can yield detachments that might mimic the attributes found on the lithic byproducts of chipped stone technologies. Lithic byproducts formed as a result of these experiments were then compared to the bend breaks and flakes from the Topper pre Clovis assemblage, and to a control assemblage of chert items that appear similar to bend breaks that were recovered from off-site, presumably natural contexts. The items that comprise the control assemblage are a product of Fort Payne chert and were recovered in 2012 from alluvial clay and colluvial silt loam deposits from a field in Williamson County, Tennessee. Analyses were designed and conducted to assess whether the attributes on bend breaks from Topper exhibit the same or similar morphological and technological attributes as those from the experimental and controlled assemblages. If the assemblages differ with respect to a set of specified attributes, it follows that they were likely formed under different processes.

Recent reports from a number of archaeological sites in the Americas have documented the occurrence of chipped stone tools and debitage from contexts that predate Clovis. (e.g. Meadowcroft, Pennsylvania. (Adovasio et al. 1999), Monte Verde, Chile (Dillehay 1997; 1999), Cactus Hill, Virginia (McAvoy and McAvoy 1997), Debra L. Friedkin, Texas (Waters et al. 2011), and Page Ladson, Florida (Webb 2006). Considerable scrutiny has been given to the geomorphological and technological integrity of these discoveries, and to date, only Monte Verde has been accepted by professionals working on the peopling of the Americas (Wheat 2012). A 2012 survey geared to assess professional opinion regarding the legitimacy of pre Clovis sites in North America found that only 15% of respondents are convinced of Topper’s acceptance as a pre Clovis site. By contrast, a total of 37% reject the age of the site as pre Clovis whereas 48% of respondents are undecided (Wheat 2012).

To be considered acceptable, pre Clovis sites must be held to extraordinarily high standards, and often undergo meticulous inspection. Artifacts of human origin must exhibit specific diagnostic attributes; specifically, those that establish behavioral intent, to be classified as a product of human lithic manufacture (Dincauze 1984; Haynes 1969). Likewise, the deposits containing these assemblages must be found in good stratigraphic context, without evidence of having been disturbed during or after formation.

The results of a geoarchaeological analysis of the Topper sediments have confirmed the separation of Clovis from the older assemblage by a "moderately well-developed paleosol" (Waters et al. 2009:1305). This separation spans approximately 60 cm of sediment, and may reflect a few hundred to a few thousands of years of deposition and pedo–genesis that stratigraphically distinguish the Clovis (13,250 cal yr. B.P.) from pre Clovis ( >13,500 cal yr. B.P) deposits.
Chapter two provides a brief summary of the timing and origin of humans in North America, with particular emphasis given to the requirements necessary for identifying sites of great antiquity. A detailed outline of the culture history of the Savannah River Valley is presented in Appendix 1 giving the major cultural trends, settlement/subsistence strategies, and types of artifacts that are considered diagnostic of each period. Appendix 1 also serves as a guide to place the archaeological components at Topper into cultural and temporal context.

Chapter three provides a description of current understanding of the paleoenvironmental and geomorphological history of Topper. Change and variation in the environment during the Late Pleistocene likely influenced the pattern and distribution of resources available for human acquisition. Therefore, a regional and site-level paleoenvironmental reconstruction may provide a better understanding of the conditions under which people may have lived over time. A description of locally available raw material resources is provided in Appendix 2. This section is followed by an account of the site stratigraphy, geochronology, and geomorphology, which places the archaeological assemblages at Topper into temporal context.

Chapter four presents a comprehensive history of all excavation conducted at Topper. This section outlines the results of yearly excavations at the site and also describe all data entry and recording methods employed over the course of site investigation. A significant contribution of this research is an in-depth description of the lithic materials that have been recovered from the site and an overview of the extensive excavation history of one of the largest Paleoindian quarry sites in North America.

Chapter five discusses the various approaches to stone tool analysis employed herein. Included in this chapter are descriptive accounts that illustrate basic lithic terminology, flake formation and fracture mechanics, and the role of flake taphonomy in the formation and
distribution of lithic assemblages. A specific point of emphasis are the methods and attributes used to distinguish natural versus cultural transformation processes, and how lithic materials can be affected by physical and chemical processes. The explicit project research design is presented in chapter six. This chapter summarizes the goals of the study, followed by a brief review of the methods and results of prior lithic analyses of the pre Clovis assemblage at Topper. This discussion is followed by an outline documenting how the research sample was selected, and what criteria were employed in choosing the attributes for analysis. As stated, the goals of this project are to determine the origin of the lithic materials identified as conchoidal flakes from the Topper pre Clovis deposits and to test the role of human agency in the manufacture of materials that were classified as bend break in the field.

Five separate lithic analyses were conducted to evaluate the Topper assemblages and are presented in Chapter 7. First, Sullivan and Rozen’s (1985) interpretation free model was employed to characterize the nature of all lithic materials from the research sample. Second, Cotterell and Kamminga's (1987) model of flake formation was used to assess lithic technology, and to determine the techniques applied in stone tool production at Topper. Potential strategies of tool production considered for this analysis include: biface and flake core manufacture by conchoidal hertzian flaking; bipolar core reduction by compression flaking; and bend fracture flaking by either bending or compression forces. Third, all tools were classified by type according to Andrefsky’s (2005) morphological typology for chipped stone artifacts. This approach was employed to identify the types of tools that were manufactured or used in specific locations onsite. The methodology was also used to distinguish whether or not there are any differences in technological strategies of tool production through time. Fourth, a microwear and edge modification analysis was conducted to evaluate whether the lithic items, both potential
bend breaks and flakes recovered from possible pre Clovis deposits at Topper exhibit patterns of use. To perform this examination a sample of potential bend break and flake tools were subjected to microscopic analysis. Patterns of use considered for this analysis include polish, striations, residue, and micro-chipping. Finally, a refit analysis examines the distribution of artifacts that conjoin to assess site integrity, particularly as it relates to the potential for postdepositional vertical and horizontal displacement of artifacts across the site.

Chapter 8 presents the results of the weathering simulation. An experimental research program was developed to evaluate whether natural processes can result in lithic detachments that resemble artifacts of human agency. Accordingly, a sample of local chert cobbles was subjected to a series of simulated weathering procedures to determine if variation in moisture or temperature might result in lithic fracture events. The results were subsequently compared to the attributes of the possible bend break and flake assemblage from the pre Clovis deposits at Topper. Moreover, the attributes of a sample of items resembling bend breaks recovered from an off-site locale were also compared to the experimental and Topper assemblages. This off-site sample (recovered from an area lacking archaeological deposits) presumably serves as a control for items formed from natural processes.

Chapters 9–11 present the results of three distributional analyses. These analyses include a cortical analysis (Chapter 9), a mass and size grade analysis (Chapter 10), and a spatial analysis (Chapter 11). These analyses were carried out to evaluate if postdepositional disturbances have altered or disturbed the distribution of lithic items at the site. The cortical analysis examines the distribution of cortex throughout the stratigraphic profile. Lithic byproducts resulting from bipolar lithic reduction are thought to produce high quantities of angular shatter, cortical pebbles, and cortical debris. These items resemble cortical pebbles that also could have formed by way of...
natural weathering or erosional processes, but can be distinguished from such processes by their occurrence in association with anvils, compression flakes, bend breaks, and other items related to bipolar production. Therefore, high concentrations of cortex are expected in deposits where bipolar reductive activities may have been carried out. A mass and size grade analysis was carried out to determine if smaller items were being reworked from original contexts into deeper deposits across the site. The spatial analysis incorporates nearest neighbor and cluster analysis to evaluate if non-random horizontal or vertical patterns exist within the Topper Clovis and pre Clovis assemblages, and to aid in establishing the processes responsible for their location of deposition. Chapter 12 presents a discussion and interpretation of the results. This chapter is followed by Chapter 13, which presents the conclusions of the study and areas where future research may be beneficial.

In addition to the individual chapters, a total of 45 appendices document the results of this dissertation. Appendix 1 offers a comprehensive culture history of the Savannah River Valley. Appendices 2–7 present data on the environmental and geochronological history of the Topper Site. Data specific to chert type and condition, site geomorphology, particle size analysis, geochronology, and pollen research are documented in these appendices. Appendices 8–16 offer data pertinent to the site excavation history. Specific appendices include the results of yearly excavations (Appendices 10,11,13,15,16), list of backhoe trench excavations (Appendix 14), and artifacts recovered from nearby quarry sites (Appendix 8). Appendices 17–21 present data relevant to site feature and level record information. Appendices 22 and 23 present site excavation maps for yearly block excavations as well as associated artifact planview and profile maps. Appendices 24–28 present site field shots as well as photographs specific to each artifact type recovered onsite. Finally Appendices 29–45 present the data acquired from and used in the
present study. Figures and tables that appear in the appendix are referenced in the text with the preceding letter “A” followed by the appendix and associated figure or table number (e.g. A1–2).

The following chapter offers a discussion of the peopling of the Americas with specific emphasis on the criteria essential to substantiate or disprove such claims.
CHAPTER II

PALEOAMERICAN ORIGINS AND THE PRE CLOVIS DEBATE

One of the most contentious debates in North American archaeology concerns the timing and origins of human entry into the North American continent. Until recently, most Paleoindian scholars have fallen into one of two camps: 1) those who favor the traditional Clovis First hypothesis, and 2) those who argue that humans were in North America well prior to Clovis, perhaps several thousand years or more prior to ca. 13,250 cal yr B.P. The Clovis first hypothesis suggests that groups of Paleoindian hunter-gatherers migrated from Siberia to North America by way of the Bering Strait land bridge into Alaska, and moved through a narrow passage that had been exposed between the Laurentian and Cordilleran ice sheets at the end of the Pleistocene (Haynes 1969, 2005; Martin 1973). The Clovis culture has long been considered by many to be the oldest well-documented culture complex to inhabit North America (Haynes 1964, et al. 2004; Bonnichsen and Turnmire 1991). Clovis hunters are assumed to have followed the distribution of megafauna or migrating fowl into North America, rapidly populating the continent, and extending as far as the southern tip of South America within a millennium (Fiedel 2000; Haynes 1966, 1980, 1982; Martin 1973).

The Clovis First hypothesis stems in large part from early to mid-twentieth century discoveries of distinctive fluted lanceolate projectile points found associated with the remains of extinct megafauna (Figure 2–1). During this time the debate over the antiquity of humans in North America was a primary topic of interest among many anthropologists. Were people in North America during the Late Pleistocene or did they arrive at some point later during the Holocene? One of the earliest documented cases of a Pleistocene human presence in the New World comes from the 12 Mile Creek site in Kansas excavated during the summer of 1895 where
Figure 2–1
Examples of Fluted Clovis Projectile Points from the southeastern U.S. (Image courtesy of Albert C. Goodyear).
a fluted projectile point was recovered in context with the remains of *Bison antiquus* skeletons (Hill 2006). At the time, this discovery went largely overlooked. Archaeological sites such as 12 Mile Creek were rooted in issues dealing with chronology. During the late nineteenth century, artifacts thought to be cultural in origin were being reported from deposits thought to be glacial gravels, loess of purported Pleistocene – age, and from deposits containing extinct fauna (Meltzer 2009:70–72, 80, 81). In spite of these reports, a number of scholars including William Henry Holmes of the Bureau of American Ethnology and Thomas Chamberlin of the United States Geological Survey challenged claims for an early Pleistocene human presence. Ales Hrdlička, a physical anthropologist with the Smithsonian Institution, also held this viewpoint into the 1920’s. Hrdlička argued that a Pleistocene human presence in the New World must be based on incontestable stratigraphic evidence and that archaeological remains must be found in geological deposits whose age is established by association with faunal remains (Hrdlička 1907). Although a number of potential sites of Pleistocene – age were identified during the late nineteenth and early twentieth century, none was found to positively fit these requirements.

Widespread acknowledgement of an early human presence in North America first occurred with the 1926 discovery of fluted projectile points in direct association with *Bison antiquus*, an extinct form of bison, at Folsom, New Mexico, (Brown 1928, 1929; Cook 1927, 1928; Figgins 1927). The first excavated Clovis point found in primary context was recovered from Burnet Cave, New Mexico in August of 1931 (Boldurian and Cotter 1999:73). In 1932 Clovis points were found at the Dent site in Colorado, although the projectile points recovered were initially assumed to represent Folsom varieties (Haynes and Huckell 2007). Clovis was first acknowledged as a definitive culture complex from the results of excavations at the Blackwater Draw Site near Clovis, New Mexico, in 1934 (Boldurian and Cotter 1999). At Blackwater Draw,
fluted projectile points were found associated with the disarticulated remains of mammoth and other extinct Pleistocene-age animals. Moreover, the discovery of blades at Blackwater Draw suggested a dependence on other artifact forms apart from projectile points. The presence of Clovis artifacts in strata below that of the Folsom artifact-bearing deposits implied that the site had been occupied by multiple culture complexes.

The discoveries of fluted projectile points in contexts associated with extinct megafauna at Folsom and Blackwater Draw disproved the then widely accepted idea of a relatively “late” (e.g. 5,000 cal yr B.P.) arrival of human populations to the Americas. Since the 1930’s Clovis sites have been identified through much of North America, and include habitation sites, quarry sites, kill sites, and cache sites (Smallwood et al. 2015). Figure 2–2 presents the distribution of known Clovis and Paleoindian sites throughout North America. By the 1960’s, advancements in radiometric dating allowed more precision in age determination and seemed to indicate that the Clovis culture not only provided the earliest evidence of Paleoindians (Meltzer 2009:5), but appeared suddenly about 13,000 B.P. A recent analysis of radiocarbon dates taken from a sample of well-dated sites suggests that Clovis, as a cultural complex, may have existed for as little as 250 years, from ca. 13,050 to 12,800 cal yr B.P. (Waters and Stafford 2007). According to Miller et al. (2013:215), who also examined the radiocarbon evidence, classic Clovis sites in North America likely range from “~13.4k to ~12.7k cal yr B.P. (11,600 to 10,800 14C yr B.P.)”.

Regardless of timing, it is conventionally believed as a result of genetic research that the initial colonizing populations ultimately had their origins in Asia, and are directly related to contemporary Native Americans (Goebel et al. 2008; Rasmussen et al. 2014). Support for the Clovis First model during the mid-twentieth century was due largely to a lack of irrefutable evidence for cultural materials that reliably predated Clovis in North America.
Figure 2–2
Selected North American Paleoindian Sites (Map courtesy of PIDBA.org).
Pre Clovis

During the late 1960’s, the Clovis First model was challenged by the discovery of an increasing number of sites having evidence of cultural materials that significantly predated Clovis, such as Valsequillo in Mexico, (Irwin Williams 1967a, 1967b; Williams et al. 1969) and Calico Hills in California (Leaky et al. 1968). At the Hueyatlaco Site in the Valsequillo Basin of Mexico human habitation was indicated by the presence of stone tools recovered from deposits dated to 250,000 cal yr B.P. (Irwin Williams 1967a). At Calico Hills California objects described as chipped stone artifacts were dated at or older than 200,000 cal yr B.P. using uranium series and fission track dating techniques (Irwin Williams 1981; Malde and Steen-McIntyre, 1981; Steen-McIntyre et al.,1981; Szabo et al. 1969). If discoveries such as Valsequillo and Calico did pre-date Clovis, then the long-held Clovis First colonization model would need to be reassessed. Critics of the legitimacy of these sites cited questionable dating techniques, geologic context, and artifact legitimacy as bases for skepticism, thus leading many in the scientific community to refute the findings (Dincauze 1984; Haynes 1973). At Calico Hills, Haynes (1973:307) questioned the character of the lithic assemblage, noting that natural processes such as rock fracturing, tectonic stresses and weathering could have produced specimens indistinguishable from artifacts. Proponents for pre Clovis sites often argued that their merits were being held to standards far beyond those given to less controversial or younger sites (Dincauze 1984).

In response to the continuing debate concerning the legitimacy of a growing body of pre Clovis sites, it became evident that a set of standards were necessary by which to objectively examine the validity of archaeological sites with reported ages greater than Clovis. Haynes (1969:714) proposed minimum criteria necessary to demonstrate pre Clovis occupations. These included: at a minimum human skeletal remains or an “assemblage of artifacts” that were
irrefutably the work of human agency (Haynes 1969:714). Furthermore, such materials must “lie in situ within undisturbed geological deposits” to verify “primary association between artifacts and stratigraphy” (Haynes 1969:714). Finally the minimum age of the site must be “confirmed by the primary association of fossils” or artifacts of known age with material suitable for reliable radiometric dating (Haynes 1969:714).

Other scholars focused on theoretical aspects of the Clovis/pre Clovis debate (Dincauze 1984). In a classic paper entitled “An Archaeological Evaluation of the Case for Pre–Clovis Occupations”, Dincauze suggested that “it is necessary to construct a logical framework from which data must undergo some form of evaluation” (Dincauze 1984:297). According to Dincauze, this could be accomplished through rigorous examination of multiple hypotheses, and subsequent testing of the implications of such propositions. This framework must also conform to an expected standard that all potential pre Clovis sites must follow (Dincauze 1984:297). According to Dincauze, many proposed pre Clovis sites were not being examined with the logical framework required to make such claims. Proponents of early sites were criticized for practicing erroneous styles of argumentation rather than providing demonstration though a framework of analysis and deduction. Dincauze suggested that any claim for pre Clovis, as with any “argument of demonstration”, must be held to scientific standards, a process of demonstration through a framework of deduction (Dincauze 1984:297). Therefore sufficient demonstration of dating, geological contexts, and artifact status above all, must be carefully considered amid the “burden of developing, testing, and disproving/accepting hypotheses” (Dincauze 1984:310).

During the 1970’s and 1980’s an increasing number of sites were discovered that provided evidence for a pre Clovis occupation of North America. At Meadowcroft Rockshelter
in Pennsylvania, excavations conducted by James Adovasio from 1973–1979 revealed an assortment of lithic artifacts including an unfluted projectile point and blades from deposits radiocarbon dated at minimum to 16,000 B.P. and possibly as early as 19,000 B.P. (Adovasio et al. 1990). Criticism of the early radiocarbon dates at Meadowcroft focused on the potential for contamination by ancient carbon from coal-bearing strata in the watershed, in addition to Holocene biota in the early deposits (Tankersley and Munson 1993), although this argument has since been refuted (Goldberg and Arpin 2000; Meltzer 2002:52).

Using the criteria set forth by Haynes (1969) and Dincauze (1984), nearly all pre-Clovis sites proved flawed in some capacity (Dincauze 1984; Meltzer 2004). However, beginning in the mid 1970’s, the Monte Verde Site in southern Chile was excavated over two decades by an interdisciplinary research team, leading to the discovery of a diverse array of preserved organic materials and lithic items from a component that dated to ca. 14,500 B.P. (Dillehay 1997, 1999). Following a site visit by leading members of the scientific community in 1997, participants agreed that the site was archaeological and that the dates were accurate, making it the first indisputable evidence for pre-Clovis on the continent (Meltzer et al. 1997).

The discovery at Monte Verde posed significant problems for the traditional Clovis First model. If Clovis people spread south upon entering the New World by an “ice free corridor”, eventually reaching the southern tip of South America by 14,800 cal years ago, then this would leave an extremely short period of time in which to populate the entire hemisphere. As a consequence, with the acceptance of Monte Verde as a legitimate pre-Clovis occupation by most scholars (Wheat 2012), conventionally held colonization models have been increasingly challenged (Bradley and Stanford 2004; Fladmark 1979; Waters et al. 2011). Stanford and Bradley (2002, 2012) proposed a colonization model whereby initial populations employed the
use of boats to skirt the North Atlantic ice caps during the Late Pleistocene, eventually arriving in North America from Western Europe (Bradley and Stanford 2004). Alternatively, a coastal migration model, widely credited to Knut Fladmark (1979), postulates that coastally adapted human groups moved rapidly down the Pacific coast from Northeast Asia, arriving in South America prior to substantial migration into the North American interior. The discovery of Late Pleistocene coastal sites including human skeletal remains at Arlington Springs on the Channel Islands of California (Orr 1962) is potential evidence for Paleoindian use of watercraft in the New World, although, as yet, no direct evidence of such craft have been recovered (Engelbrecht and Seyfert 1994; Jodry 2005). Other sites on the U.S. west coast also provide evidence for human habitation prior to Clovis. At the Paisley Cave Site in Oregon, the recovery of mtDNA from human coprolites directly dated to 14,300 cal yr B.P. marks the earliest example of genetic-based directly obtained pre Clovis evidence in North America (Gilbert et al. 2008). Like many other claims for pre Clovis, the findings at Paisley Cave are controversial and have been met with skepticism by some scholars (Fiedel 2014; Fiedel and Morrow 2012).

While the search for additional sites and more dating is warranted to corroborate claims of a pre Clovis occupation in North America, it is also beneficial to continue to scrutinize the material culture and data that archaeologists already have accumulated. One of the most interesting characteristics of North American pre Clovis sites is the apparent inter-site variability among the technologies of reported artifact assemblages. Whereas Clovis sites are typically identified by a suite of iconic chipped stone reduction strategies that include the manufacture of fluted bifaces and prismatic blades, earlier assemblages appear to lack evidence of any pan-regional diagnostic production strategies. The extensive list of pre Clovis artifact forms includes stemmed projectile points, bipointed bifaces, crescents, modified bone, flake and pebble tools,
bipolar cores, and bend and radial break flakes, in addition to unfluted bifaces and prismatic blades and bladelets (Collins et al. 2013; Jenkins et al. 2012; McAvoy and McAvoy 1997; Waters et al. 2011). The assemblage variation suggests that several terminal Pleistocene socio-economic adaptations were present and that no single highly distinctive material culture may have been in North America prior to Clovis. Given the variety of assemblages presumed to predate Clovis, studies geared toward discerning the degree to which these groups may have interacted have proven problematic.

In light of the prospect of significant variation among pre Clovis assemblages, Collins et al. (2013) examined the spatio/temporal variance in cultural patterns from 27,000–13,000 cal B.P., and identified seven cultural manifestations distinct from Clovis over this interval. These patterns (Table 2–1) are based primarily on toolkit composition and the geographical placement of sites on the landscape. In brief, Collins et al. argued that the eastern margin of North America was inhabited significantly earlier than the western margin (Collins et al. 2013). Collins et al. also brought to attention important questions regarding terminology. Until recently, the popular term for the period of North American habitation prior to the advent of Clovis lithic technology has been “pre Clovis”. However, this term implies that all early cultures eventually led to Clovis, which is presently unverified. Contrary to what the name implies, the term pre Clovis should not be employed to denote a direct, genetic, or technological connection to Clovis, but simply that such sites predate the traditionally held timing for initial human entry into the continent. As a result, recent publications have presented alternative terms such as Older than Clovis (OTC) (Collins et al. 2013), Discovery Period (Waters and Stafford 2013), or Early Paleoindian

(Anderson et al. 2015) that do not have the connotation of a direct or genetic relationship to Clovis. Other terms such as proto Clovis have been used to imply a cultural affinity based on technological relatedness (Haynes and Huston 2014).

Fiedel (2013) suggested that many archaeologists have uncritically accepted the material culture recovered at sites dating prior to 13,200 cal yr B.P. as artifactual without consideration of the potential natural processes that could have also created or redistributed these purported assemblages. At Cactus Hill, the zone separating the Paleoindian from apparently older pre Clovis deposits has been intersected by artifacts from Archaic deposits resulting from down-drift from the overlying deposits (Fiedel 2013:244). At the Debra L. Friedkin Site, the Clovis and reportedly older pre Clovis deposits are separated by a thin layer of sediment, a few centimeters in thickness, and critics argue that artifacts have migrated downward through small cracks in a vertisol matrix resulting in artifact displacement from original context over time (Fiedel 2013). Fiedel (2013:344–345) describes the bend break and microlithic items at Topper as an assemblage that could have formed as the result of natural processes. Accordingly, the numerous chert fragments from these deposits could have formed by natural breakage events that mimic human manufacture or as the result of down-drift. Using this logic, the best evidence for legitimate pre Clovis assemblages are those assemblages that consist of readily identifiable tool types such as bifaces and blades that are similar to Upper Paleolithic assemblages and are found in contexts that pre-date Clovis. Unfortunately, because such artifacts are also common to Clovis assemblages, any determination as to what artifacts reflect pre Clovis and what do not from a mixed assemblage cannot be ascertained. Because of the potential similarities in toolkit composition and the potential for mixing, Bryan (2004) has argued that archaeologists should abandon their dependence on finding diagnostic tools when seeking evidence of early sites.
However, because there are no diagnostic pre Clovis artifact forms, or assemblages that would allow meaningful comparisons, this solution is also problematic as it offers no method to qualify the materials as legitimately pre Clovis. One objective of this dissertation is to differentiate between the byproducts of naturally produced lithic assemblages from the potential byproducts of bipolar and biface technologies using technological attribute analysis.

One common characteristic of many pre Clovis sites is that the reported assemblages either consist of numerous presumably naturally fractured items that lack evidence of cultural attributes or when the tools from such sites do exhibit such attributes, the associated assemblages also consist of much less debitage than would be expected to have occurred in their production. As Fiedel (2013:344) notes, “Why do pre Clovis tool-making activities produce so much less debitage” than their later counterparts? If similar tool forms were being produced by these cultures then the expectation favors similar debitage patterns. However, the production of a pre Clovis toolkit that is dissimilar to Clovis in composition should also result in debitage patterns that are unlike Clovis. Moreover, lithic production activities that were focused on the manufacture of bipolar or non-bifacial tool forms could result in lithic byproducts that have attributes consistent with debris as opposed to flakes. By this reasoning, it might be more beneficial to examine each assemblage, noting the ratio of potential pre Clovis tools to debris, and subsequently comparing the results to the ratio of Clovis toolflake patterns.

It is essential that any potential pre Clovis site must undergo a rigorous standardized set of investigations to assess claims of pre Clovis occupation. Haynes (1969:714), Stanford (1983:65), and later Dixon (1999:48) have proposed five questions that must be answered if a site is to be considered a legitimate pre Clovis occupation.
1. Are there artifacts that are clearly the product of human manufacture?

Artifacts of anthropogenic origin must exhibit specific diagnostic attributes, those that establish behavioral intent, in order to be classified as a product of human lithic manufacture.

2. Is the recovered material within clear stratigraphic context?

The deposits containing the proposed assemblages must be shown to be stratigraphically intact, without evidence of having been disturbed by post depositional or natural site formation processes.

3. Are there reliable, concordant, and stratigraphically consistent radiocarbon or other absolute dates from the deposit?

4. Are paleoenvironmental studies consistent with ages assigned to the site?

5. Are there human remains that are reliably dated older than 13,500 B.P. (Dixon 1999:48)?

If there are no human skeletal remains at a proposed pre Clovis site, then the first four questions must all be answered positively if a site is to be credibly considered pre Clovis in age and of human origin. The present study examines the Topper assemblage with consideration of the preceding questions. Since no human skeletal materials have been recovered from the Topper that predate 13,500 cal yr B.P., this dissertation examines the assemblage in relation to questions 1 through 4. The following chapter provides a description and reconstruction of the paleoenvironmental and geological history of the Topper Site with emphasis placed on the stratigraphy and depositional history.
CHAPTER III

GEOMORPHOLOGY AND PALEOENVIRONMENT

Topper’s Geography and Physiography

The Topper Site (38AL23) is situated at 33° N latitude within the central Savannah River valley of the Atlantic Coastal Plain approximately 80 km from the Atlantic coast (Figure 3–1). The site is located in the Upper Atlantic Coastal Plain physiographic province, which is bounded to the north by the Piedmont physiographic province and the Orangeburg Scarp to the south (Nystrum et al. 1991). Topper is part of a larger prehistoric quarry complex identified on the property of the Archroma Corporation, formerly owned by the Clariant and Sandoz Corporation in Allendale County, South Carolina (Goodyear et al. 2007) (Figure 3–2). More specifically, Topper is one of thirteen terrestrial chert quarries having Tertiary-age lithic deposits discovered in this part of the drainage that are situated along the bluffs that overlook the river (Figure 3–3). The site occupies multiple topographic features of the landscape, including a floodplain, an alluvial first terrace (T1) formed by the entrenchment of the Savannah River and lying approximately 99m above sea level, a second terrace (T2) situated at 101.5m above sea level composed of colluvial slopewash sands, a hilltop above the terrace that is part of the Coastal Plains uplands, and a hillside slope located between the terrace and the hilltop, and to the North of Little Sweet Water Creek (Goodyear et al. 2007; King 2012; Miller 2007, 2010; Waters et al. 2009). Above the terraces, the hillside slope is covered by late Quaternary colluvium and eolian sediments.

Archaeological components at Topper have been recovered from the second terrace, the hillside and hillside slope. The floodplain and terrace portions of the site were originally assigned a site number of 38AL23, with the adjacent outcrop and hilltop designated 38AL139.
Figure 3–1
Figure 3–2
Location of the Topper Site (38AL23) relative to the Archroma corporation property boundary (highlighted in yellow), Allendale County, South Carolina.
Figure 3–3
Location of the Topper Site (38AL23) and associated chert quarry locations identified by Goodyear and Charles (1984) and discussed in the text (figure adapted from Goodyear and Charles 1984).
However, extensive investigations revealed that the archaeological components were likely related. As a result, the site number formally given as 38AL139 for the hilltop was eliminated and all areas were subsumed under the designation 38AL23.

The focus of this dissertation is on lithic materials buried within the first and second terrace and overlying sediments adjacent to the floodplain. This area of the site measures approximately 300m north to south and 200m east to west. The second terrace in this location consists of eroded tertiary bedrock, and a dark Pleistocene overbank unit composed of silty clay that is referred to by Goodyear as the Pleistocene Terrace. This is overlain by Pleistocene-aged alluvial sands, referred to as the Pleistocene Sands. Above the Pleistocene Sands and extending to the surface is the Holocene colluvium, otherwise referred to as the Holocene Terrace (Figure 3–4).

*Geology and Lithic Resources*

**Southeast**

Raw material for the production of stone tools was a valuable commodity for prehistoric peoples. One raw material type that has been found to be suitable for chipped stone tool production is chert. Chert is a form of sedimentary rock that is composed of microcrystalline quartz. The cherts that are common in the southeastern U.S. Coastal Plain consist of two distinct forms that result from two different processes of silicification (Upchurch, et al. 1982: 38–40). One type of chert is composed largely of opaline, and is formed in marine sediments by the breakdown of diatoms, which secrete silica leading to the formation of chert (Goodyear and Charles 1984:2). These cherts are inferior in tool-making quality as they are “brittle and weak when flaked” (Goodyear and Charles 1984:2). As a result, opaline cherts were not typically used by the prehistoric peoples of the area. A second type of chert, and preferred by prehistoric peoples of the region for the manufacture of stone tools, is formed from replaced limestone.

Highlighted areas reflect provenience from which study sample was selected.
(Goodyear and Charles 1984). Such cherts are described as developing when groundwater transports silica that formed in diatoms, and are physically stronger because “the silica was in the form of quartz during the replacement process” (Goodyear and Charles 1984:2). The cherts from the Savannah River Valley, including those local to the western Allendale County, area are examples of this process and would have been preferred raw materials of choice by prehistoric peoples of the area.

**Chert from the Savannah River Valley**

A significant number of chert quarries occur within the Middle Coastal Plain of South Carolina along the eastern boundary of the Savannah River. The chert outcrops that exist in this region are defined as Tertiary-aged, belonging to the Flint River Formation, and are classified as a silicified grainstone (Goodyear and Charles 1984; Upchurch 1984). Chert outcrops of this formation stretch northeast from Florida, across the Coastal Plain of Georgia, and terminate near Allendale County, South Carolina, at the intersection of the Savannah River. The Flint River Formation served as the primary source of high quality chert in South Carolina. Locally, chert from this formation is referred to as Allendale.

Localized deposits of chert from the Savannah River Valley are often referred to as Allendale, and are described as a “yellow, brown, waxy homogenous chert” (Upchurch 1984:15). Four characteristics are recognized in the classification of Allendale chert 1) a homogenous structure with limited evidence of fossils that would disrupt isotropy, 2) a range of colors including dark brown, tan, red orange yellow white and frequently translucent, 3) a change in colors to pink, red, and blue when after thermally altered specimens have been flaked (Anderson 1979:223), and 4) a strong predisposition to weathering resulting in a loss of silica and color, resulting in the formation of a yellow-white cortical surface (Goodyear and Charles 1984:5).
Thermoluminescence analysis has been offered as a valuable means of identifying whether or not a sample of chert has been heated, although the method cannot differentiate intentional from unintentional thermal alteration (Anderson 1979:224). Allendale chert is typically found along the eroded margins of bluffs, exposing the outcrop. Because of its properties, Allendale chert was a key source of tool-stone for prehistoric knappers of the region, and was geographically limited to the surrounding counties, primarily within a few miles of the Savannah River (Goodyear 1984).

*Allendale Chert at Topper*

The terrestrial chert outcrop at Topper is situated along the hillside slope exposed on the escarpment that overlooks the alluvial terrace (Figure 3–5). This outcrop is exposed as a result of erosion, and having been used as a prehistoric quarry. At Topper, Allendale chert seems to have been the preferred lithic material, having been identified from Paleoindian, Archaic and Woodland deposits at the site. Allendale chert can form in at least two morphological varieties: as nodules or as tabular slabs. The exposed chert outcroppings at Topper are typically nodular rather than tabular in form, with nodule maximum diameters having been found to range in size from 300–500 mm” (Smallwood 2010:84). According to Smallwood, nodules often have “voids and flaws of cortical-like material that have never silicified” (Smallwood 2010:84). Specimens greater than 500 mm in diameter may not have been available in abundance at Topper, thus preventing prehistoric knappers from producing lithic tools of this size. Moreover, the occurrence of voids in Allendale chert limits the successful detachment of decortication flakes of significantly large sizes. Appendix 2 presents various forms of chert recovered at Topper, the adjacent riverbed, and the results of a material condition assessment to determine the quality of each variety identified.
Figure 3–5
Location and characteristics of chert outcrop at the Topper Site (38AL23), Allendale County, S.C. Top: Map of site (courtesy of Shane Miller). Bottom left: Site stratigraphy (adapted from Waters et al. 2009:1302). Bottom right: exposed chert cobbles on the hillside slope.
Apart from the terrestrial cobbles, additional sources of raw material at Topper were chert cobbles from the Savannah riverbed, and eroding from the bank of Little Sweetwater Creek, an ephemeral stream that drains the upland Coastal Plain and forms the southern margin of the site (Figures 3–3, 3–5)(Goodyear 1986:3). Little Sweetwater Creek travels perpendicular to the river, carving through the terrace along the southern margin of the site. The creek forms a small floodplain between the terrace and the uplands (Goodyear 1986:3). During a 1984 survey, an abundance of chert cobbles was found eroding from the bank of this drainage (Figure 3–6). It is thought that by the time Clovis populations arrived in the Coastal Plain of South Carolina, the elevation of the Savannah River had already dropped and exposed the chert cobbles from the river drainage (Goodyear 2000). The cobbles recovered from the river contain a “distinctive butterscotch colored cortical surface, unlike those items recovered from terrestrial sources” (King 2012:18). The difference is assumed to have been caused by repeated polishing by way of water action, which erodes the cortex revealing the glossy outer rind (Goodyear 2007b:14). Such processes result in the formation of patination on the exterior surfaces of lithic items when subjected to submerged fluvial contexts. The patina is formed when the material is exposed to the chemical “leaching of soluble constituents leaving behind the more resistant quartz grains” (Parish 2010:9). According to Howard (1999:293), river patination does not result directly from silica abrading silica, but is a more complex process involving the initial abrasion of the lithic surface topography and subsequent accelerated dissolution. Therefore lithic nodules that have been exposed to more pronounced stages of patination typically have a minimal surface topography, and are extremely smooth (Howard 1999:293). Moreover, because river patina does not display evidence of stages of development or polishing, an artifact’s age cannot be established from the extent or degree of river patina (Howard 1999). Unlike terrestrial chert,
Exposed chert cobbles eroding from the bank and creek bed of Little Sweetwater Creek along the Southern margin of the Topper Site (Image courtesy of Albert C. Goodyear). The location of Little Sweetwater creek is shown in Figures 3–3 and 3–5.
which typically forms in nodules, chert that is exposed by the river (river stained chert) will occasionally occur in tabular form. The tabular examples could have formed as a byproduct of erosional processes resulting from the river or when silica layers were covered by sediments and subsequently subjected to significant pressures.

**Regional Soil Classification**

Soils at Topper are classified as belonging to one of two formations: the Lakeland B series, and the Tawcaw Chastain complex (Figure 3–7). The Lakeland series consists of well drained soils that formed in sandy marine sediments (Eppinette 1993:74). These soils are typically found along the tops and slopes of upland ridges, are moderately to strongly acidic and have an argillic horizon (Eppinette 1993). The soil series in the region are made up of three horizons; an Ap from 0–6 inches that is composed of loose sand with a smooth, clear boundary; a C1 horizon from 6–70 inches composed of reddish yellow single-grained loose fine to medium-grained sand; and a C2 horizon from 70–85 inches with reddish yellow single-grained loose sand (Eppinette 1993). Lakeland series soils form the hilltop and hillslope portion of the Topper Site. The floodplain deposits at Topper are composed of soils that make up the Tawcaw Chastain complex. Tawcaw soils are described as poorly drained soils that formed in fluvial sediments typically found on the flood plains of the Savannah River, where there is less than 2% slope (Eppinette 1993:81). They are characterized as having an Ao horizon from 0–15 inches that is composed of silty clay loam. A Bw1 horizon occurs from 15–20 inches and consists of yellowish brown silty clay loam. An underlying Bw2 from 20–55 inches has been classified as comprising strong brown clay with fine dark concretions (Eppinette 1993:81). The base of the soil ranges in depth from 55–65 inches and consists of light grey silty clay loam.

Fluvial geomorphic systems of the Lower Southeast and impact on human life-ways

Paleovegetational changes during the Pleistocene were influenced by changes in the structure of riverine systems. The Topper Site is situated adjacent to a chute channel of the Savannah River, one of the major fluvial systems that drain the southeast Coastal Plain. Throughout the Late Quaternary, episodic changes in paleoenvironmental conditions caused major rivers in this region to transition from braided to meandering (Leigh 2006; Leigh et al. 2004). Based on radiocarbon and luminescence dating, Leigh suggests that these systems transitioned to meandering from 15,000–16,000 cal yr B.P., and reflect “shifts in regional vegetation patterns towards warmer and wetter conditions than during the preceding Late Pleistocene full glacial” (Leigh 2006:159). A transition from cold dry Savannah biomes to moist cool mixed forests at 16,000–15,000 years B.P. corresponds with change in the pattern of river structure (Leigh 2008). The development of dense vegetation coinciding with warming climate during this period reduced erosion and sediment yield in the drainage systems of the southeastern Coastal Plain. The rivers subsequently down-cut to the level of the modern floodplain by 15,000 cal yr B.P. If peoples were occupying areas of the southeastern Coastal Plain during this period, then changes in climate and hydrology could have affected prehistoric settlement/subsistence systems, specifically by altering the placement and distribution of plant resources that were part of the diet and technological toolkit. Leigh suggests that archaeologists interested in identifying Paleoindian and pre Clovis sites should focus search efforts to areas of the landscape where Pleistocene terraces are adjacent to braided river channels or large paleomeanders (Leigh 2008). Figure 3–8 presents a map showing the location of the Topper Site relative to the modern Savannah River and the location of former braided river channels formed during the Late Pleistocene.
Figure 3–8
Map showing the location of the Topper Site and former braided Savannah River Channel.
Topper Site Geomorphology

Although prior geological studies define the stratigraphy of the Topper Site (Goodyear and Foss 1993), work began in 1999 to document the strata containing the pre Clovis component at the site. This work was conducted by a team of scientists led by Dr. Michael Waters and ultimately resulted in a detailed description of the site stratigraphy and geomorphological contexts. Waters et al. (2009) defined three major stratigraphic units (1–3) at Topper, which comprise the Late Quaternary alluvial and colluvial deposits (Figure 3–9). Appendix 3 presents a generalized profile of the Topper stratigraphy. The appendix offers an illustration of the alluvial stratigraphy, highlighting each geological unit defined by Waters et al. 2009. These units are referenced throughout the dissertation when discussing the contents of assemblages recovered from different elevations within the profile. All archaeological materials at Topper rest within these units, which lie unconformably against a weathered tertiary bedrock, consisting of red colored deposits of sand silt and clay (Waters et al. 2009:1303). Each of the three units is further subdivided into minor units.

Unit 1, lying atop the eroded bedrock, is the oldest unit and consists of sand (1a) superimposed by gray silty clay sand (1b). This unit is described as a “fining up sequence”, composed of sediments that were periodically deposited by the meandering channel of the Pleistocene Savannah River (Waters et al. 2009:1303). The characteristic fining up of Unit 1 was also documented by Harris et al. (2010), who conducted a particle size analysis of the alluvial and colluvial deposits. The fining up sequence is evident in Figure 3–10 as a decrease in mean particle size indicated in the right column of the lower profile. The results of the particle size analysis are summarized below and detailed in Appendix 4.
Three major stratigraphic and arbitrarily assigned units at Topper. Stratigraphic units defined by Waters et al. 2009:1304 (at bottom and indicated by numerals). Image at top courtesy of Albert C. Goodyear.
Results of particle size analysis of Pleistocene Sands and Pleistocene Terrace at Topper Site
Top profile (Pleistocene Sands) Western profile wall of N246 E138. Bottom profile (Pleistocene Terrace) Western profile wall of the N45 E142 gridline. Results demonstrate a fining up sequence for the Pleistocene Terrace indicated by the decrease in mean sediment particle size illustrated in the column at right. (Image adapted from Harris 2010:1).
Unit 1 comprises the sediments referred to by Goodyear as the Pleistocene Terrace. The older subunit 1a represents periods when fill was deposited within the channel itself. A palynological analysis of a sediment core recovered from the base of unit 1b and intruding into unit 1a, documented below and in Appendix 7, resulted in the identification of multiple plant taxa with evidence for change in the distribution and occurrence of each type through the core profile. However, no evidence of cultural materials has been observed within the sediments from unit 1a. Unit 1b represents a younger sequence of overbank deposition (Waters et al. 2009). Unit 1b consists of the Pleistocene Terrace deposits from which Goodyear observed a presumed hearth feature that predates 50,000 cal. yr. B.P., and has claimed artifacts produced by human agency also occur in these deposits (Goodyear 2005).

Unit 2 is divided into three subunits (Figure 3–9). Unit 2a is composed of gravel and sand deposited by colluvial processes, and occur at the margin of the erosional scarp of the hill-side slope (Waters et al. 2009:1303). The deposits that make up unit 2a potentially accumulated at the base of the erosional scarp as weathered chert cobbles that were dislodged and transported down the side of the slope that formed the edge of the channel (Waters et al. 2009:1303). Unit 2a, for the purpose of this study, is referred to as the Lower Pleistocene Sands.

Unit 2b consists of sand with interspersed gravel lenses, and overlies the weathered surfaces of the tertiary bedrock that forms unit 1b (Waters et al. 2009:1304). Waters et al. (2009:1304) found that the north-south trending gravels in unit 2b occur within small channels (50–140cm wide) that were deposited in a fluvial environment when the braided paleo Savannah River flowed parallel to its present course. Goodyear reported chert artifacts of pre Clovis age within the sands of unit 2b (Waters et al. 2009:1304). Unit 2c consist of gray silty clay that forms irregular “lenticular masses” that are 1–2m in length and 0.5m in thickness (Waters et al.
Waters et al. (2009:1304) suggest that these masses of sediment either represent overbank flood deposits that formed a more or less continuous floodplain that was disturbed by natural taphonomic processes, or represent isolated sediments that accumulated in channels that once served as the sandy Pleistocene floodplain surface. Unit 2c represents the last time sediments were deposited on the site as a result of fluvial processes. For the purpose of this study, units 2b and 2c are otherwise referred to as the Upper Pleistocene Sands.

Unit 3 overlies unit 2, and was produced by colluvial processes resulting from the erosion of sediments from the adjacent hillside slope and their deposition onto the terrace surface. Unit 3 is composed of two subunits. Subunit 3a, the oldest, occurs in two places at Topper: at the base of the hillside slope, and immediately below subunit 3b 10m to the west where the flood plain begins to level out. Subunit 3a is composed of brown silty sand with approximately 70cm of soil development. This soil horizon is described as having “weak structure with clay films on the ped faces”, and represents the local deposition of sediments on the “terrace tread” (Waters et al. 2009:1304). For the purpose of this study, unit 3a is referred to as an indurated pedogenic feature that separates the Holocene and Pleistocene deposits at the site. In 2012 Dr. John Foss of the University of Tennessee took sediment samples from unit 3a in an effort to determine how it originated as well as its age. The pedogenic feature is thought to have formed as a result of the river scouring much of the alluvial deposits from the terrace tread, and thus leaving behind the remnant of an old surface. The presence of high quantities of clay coatings on the sand grains present within the feature imply the presence of soil formation (pedogenesis), and indicate that the feature originally formed during a period of landform stability. These findings suggest that the pedogenic feature represents a period of long-term landform stability that separates the
sediments resting on the Pleistocene Terrace surface from the sediments contained within the Holocene colluvium above.

Subunit 3b is a ubiquitous layer of silty sand with occasional angular gravels that become more frequent toward the hillside-slope. The uppermost portion (60cm) of subunit 3b is composed of a “pedogenically altered Bw horizon” below a 20cm-thick A horizon (Waters et al. 2009:1304). Goodyear identified Clovis artifacts at the base of subunit 3b with an overlying stratigraphically intact cultural sequence above (Goodyear 2001). For the purposes of this study, subunit 3b is otherwise known as the Holocene Terrace.

The sedimentological contexts of the Quaternary deposits at Topper, as noted, have been described in detail by Harris et al. (2010) based on particle size analysis of a column sample from the ground surface to the base of the archaeological excavation (Figure 3–10). This analysis found two clear stratigraphic units: a lower alluvial phase represented by a fining upwards sequence that rests below a colluvial phase. The alluvial phase corresponds with the Pleistocene Terrace and Pleistocene Sands, whereas the colluvial phase represents the Holocene Terrace. According to Harris, the base of the alluvial profile (beginning at 95.40m) is coarse, with fining upwards through the alluvial deposits (Harris et al. 2010:1). This profile indicates a lowering of energy through time. A break is evident between the lower floodplain deposits and upper colluvial deposits at elevation 97.10m. This break forms a transition between the Pleistocene Terrace and the overlying Pleistocene Sands above, and forms the surface on which large chert boulder clusters have been observed. Immediately above this break are graded beds evident as jagged features in the mean particle size profile at 97.20m. Within these beds and gravel lenses, King (2011:112) identified chert flakes that were recovered below the Clovis deposits and could
represent an older occupation at the site. Above the bedding layer and extending into the Clovis deposits above, the sediments are relatively “homogenous in nature” (Harris et al. 2010:1).

In 2004 Larry West (n.d:1) conducted a detailed geomorphological analysis of a backhoe trench known as BHT17 that had been excavated into the Pleistocene Terrace drainage the prior season. The southwest corner of this trench was located at the intersection of the N243 E140 gridline and is approximately 2m x3m x 4m in size (Figure 3–11). Figure 3–11 offers a map that shows the location of backhoe trench 17 and also gives the provenience location for all materials analyzed for this dissertation with the exception of the 2010 4m x 4m block. West conducted a geomorphological study to provide the context for a presumed hearth feature (F91) that had been encountered at the base of the Pleistocene Terrace excavation at elevation 97.35m. For this analysis, nine sediment samples were taken along the gridline from N246 E142 and extending from the top of the alluvial terrace to the base of Feature 91. According to West, the upper two horizons from 97.32–96.93m reflect a paleosol with weak structural development and evidence of clay translocation. The top four sediment samples examined (97.32–96.37 m) include evidence for redox concentrations. Also referred to as redoximorphic features, these concentrations are sediments that form under oxygen – reduced conditions such as aquatic environments. At Topper the concentrations are typically yellowish brown in hue, and are sandier than the surrounding clayey sediment matrix. Figure 3–12 shows the redoximorphic features in the uppermost portion of the terrace profile. The sediment samples taken from 96.37–95.76 m in depth consist of light grey, massive friable sandy loam at the top to loamy sand toward the bottom. Redox features are again present in the deepest three sediment samples (95.76–95.33 m). These sediments consist primarily of sandy clay loam. From 95.41–95.33 m, the deepest sample, the sediment transitions to a relatively coarse, light yellowish brown sand.

Based on the geoarchaeological and sediment analyses, the Topper stratigraphy has been well-defined. The stratigraphic units and sub-units discussed above are defined based upon sediment composition and depositional history. However, because excavations at Topper were not carried out according to geological units, but were arbitrarily defined in 5 or 10cm levels within the Holocene and Pleistocene deposits, a separate nomenclature was incorporated and is presented in Figure 3–9. For the purpose of this study the alluvial terrace at Topper (from top to bottom) includes the Holocene Terrace, the Pleistocene Sands, and the Pleistocene Terrace. The Holocene Terrace ranges in depth from 99.0 m to 98.0 m in depth and includes Waters unit 3. The Pleistocene Sands underlie the Holocene Terrace and are sub-divided into the Upper Pleistocene Sands (98.0 m–97.60 m), and Lower Pleistocene Sands (97.60 m – 97.0 m). The terms Upper and Lower should not be confused with, and do not reflect specific geological time periods, but instead are employed to differentiate the vertical location and placement of the deposit in the ground. The Pleistocene Terrace underlies the Pleistocene Sands and is separated into three sections: the Upper Pleistocene Terrace (97.0 m – 96.50 m), the Middle Pleistocene Terrace (96.5 m – 96.0 m) and the Lower Pleistocene Terrace (96.0 m – 95.25 m). Likewise, the terms Upper, Middle and Lower do not reflect chronological periods, but serve to arbitrarily differentiate the deposit with regard to the vertical site grid.

Attempts at dating the Topper sediments have met with a number of difficulties. Because of the acidic nature of the sandy sediments, organic materials such as bone and wood, do not often survive in large quantities at Topper (Goodyear 2000). Moreover, where such materials are present, the probability is high that they, in addition to charcoal, could have been introduced by bioturbation or movement by way of translocation through the sandy sediment from modern or recent contexts into older sediments. Waters (et al. 2009:1304) found that organic materials can
form as *in situ* lignified plant remains that were preserved in rare reducing environments that escaped oxidation by the vertically fluctuating water table. In the section that follows the chronological history of the Topper Site is given based on radiometric and Optically Stimulated Luminescence (OSL) dating.

**Topper Site Geochronology**

Initial research endeavors to date the sediments of the alluvial Terrace at the Topper Site were carried out in 1998. In an effort to find charcoal suitable for radiocarbon dating, the Pleistocene Sands at 2m below ground surface were screened through window mesh and any charcoal fragments observed were collected for dating. This process resulted in the recovery of four samples that each returned dates of less than 2900 $^{14}$C yr B.P. (Goodyear 2001:11). Appendix 5 presents published Accelerated Mass Spectrometry (AMS) and OSL dates from Topper. Given the complete Holocene stratigraphic sequence above, it was likely that the charcoal recovered derived from bioturbated or translocated sediments from the overlying Holocene deposits. According to Goodyear (2001) these results indicated, at least at the time, that there was “essentially no old *in situ* charcoal available for dating” (Goodyear 2001:11). In 1999 a team of geoscientists led by Dr. Michael Waters undertook research to define and date the stratigraphy at the site using radiometric and luminescence dating techniques. A series of backhoe trenches was excavated to expose the stratigraphy of the terrace. Figure 3–13 gives the location and cross sections of these backhoe trenches. From these excavations Waters et al. (2009) was able to identify a series of stratigraphic units that they correlated with the site’s archaeology (Waters et al. 2009; King 2012). Sediment samples were subsequently collected from the profile walls of these trenches to provide the age estimates of the geological deposits.
Figure 3–13

(Waters et al. 2009:1302). Figure 3–14 shows the provenience locations of AMS radiocarbon dates from the Alluvial Terrace at Topper Site.

Waters et al. (2009) provided a detailed assessment of 13 radiocarbon and 18 luminescence dates obtained from the geologic units at the site (Tables 3–1 and 3–2). The radiocarbon dates were obtained from organic materials that derive from three sources: charcoal that represents modern plant material that was moved downward by bioturbation (n=1); wood and plant macrofossils recovered from unit 1a that are at minimum 51,000 $^{14}$C yr B.P. (n=4), and from humic acids recovered from floodbasin sediments and paleosols from units 1 and 2c that range in age from 6,500–20,000 $^{14}$C yr B.P. (n=8) (Waters et al. 2009:1305). According to Waters et al., all samples were “processed for radiocarbon dating by using either standard pretreatment methods or modified techniques that evaluated diagenesis” (Waters et al. 2009:1305).

Unit 1a returned four dates in excess of 51,000 $^{14}$C yr B.P. years based on woody plant material, and hickory nut shell. An additional four humic acid samples resulted in dates ranging between 44,000 and 50,000 $^{14}$C yr B.P., and represent a minimum age for this unit. Two humic acid samples taken from unit 1b returned dates of 20,860$^{+/-}90$ and 19,280$^{+/-}140$ $^{14}$C yr B.P. and are also thought to represent a minimum age for this unit as well (Waters et al. 2009:1305).

In addition to the radiocarbon dates, 18 luminescence dates were acquired from sediments from the Topper terrace (Table 3–2). Luminescence dating is used to date the last time a given sediment sample was exposed to sunlight, and is employed to establish the timing of burial events. The technique has been used to obtain an age for sediments that are less than 200,000 years old (e.g. Forman et al. 2000). Accordingly, sediments, when exposed to solar light for a period of 10–60 minutes, results in the discharge of much of the previously stored

*D.B.D. refers to Depth below datum (m); D.B.S. refers to Depth below surface.
luminescence in a given mineral grain (Waters et al. 2009:1306). After burial, sediments do not absorb additional ionizing light. The decay of naturally present radioisotopes of U, Th, and K lead to the formation of “free electrons that are trapped in crystallographic charge defects in silicate minerals” (Waters et al. 2009:1306). The strength of luminescence emissions produced from the stimulation of minerals when light recombines with the stored charge can subsequently be calibrated and measured in the lab, yielding a comparable dose and ultimately a luminescence age (Waters et al. 2009).

At Topper, luminescence dating was undertaken on samples from Units 2 and 3. Single aliquot methods were employed to determine the age of the coarse grain fraction whereas the multiple aliquot technique was used to date the fine-grained fraction (Waters et al. 2009). Of the samples obtained, four “finite” ages were produced for the colluvium of Unit 3, and returned dates ranging from 13,200+/-1,300 to 7,300+/-800 yr B.P. (Waters et al. 2009:1306). Samples from the Unit 2a alluvium produced an age of 37,200+/-3,300 years, whereas Unit 2b produced two dates that range from 14,000+/-1,200 years to 14,800+/-1,500 years ago.

Based on the combined stratigraphy and dates obtained from the sediment samples from the analysis of Waters et al. (2009) dates, the Late Quaternary history of the Topper was reconstructed. To summarize Waters et al. (2009:1309), sometime prior to 55,000 years ago the Savannah River deposited alluvium atop the tertiary bedrock, forming the overbank sediments that comprise Unit 1. This was followed by a period of soil formation (1b) and subsequent “fluvial scouring and erosion of these soils as Unit 1b was “truncated” (Waters et al. 2009:1308).

Unit 2a then formed sometime between 15,000 and 55,000 years ago atop this scoured terrace as a result of colluvial accumulation adjacent to the channel edge, followed by alluvial deposition by the braided Savannah River system “across much of the site” (Waters et al. 2009:1308). The
top of Unit 2c formed as the result of overbank deposition and represents the last time flooding occurred onsite approximately 15,000 cal yr B.P. Evidence for soil formation in Unit 2c reflects a 2000-year period of pedogenesis once the Savannah River “down cut and abandoned the floodplain” (Waters et al. 2009:1308). During the Terminal Pleistocene and Early Holocene, colluvial processes were the dominant form of deposition at Topper, resulting in the formation of Unit 3. According to Waters et al. (2009:1308), the luminescence ages obtained from Unit 3, and taken from sediments containing Clovis artifacts, are an indication that initial colluvial processes began at the site approximately 13,000 cal yr B.P., and have continued through the Holocene.

Recent developments in luminescence dating have allowed for greater control over the number of individual grains luminescence dating can measure. Rather than measuring many grains and taking an average date, it is now possible to lessen the variability through single aliquot analysis, also known as the single aliquot regenerative dose (SAR) and first recommended by Murray and Roberts (1998:503–515). The technique is considered robust compared with traditional multiple aliquot techniques (Murray and White 2000).

Prior to 2002, OSL dating attempts of the Topper deposits were conducted predominantly using multiple aliquot methods. These techniques are “not sensitive enough to reliably date populations of sand grains” and can result in relatively large age brackets (Goodyear 2011: 6). A recently developed, single grain technique is more robust, provides an improvement over older luminescence techniques, and is used to provide a more refined chronological history of the Topper deposits.

In 2010 and 2012, 23 sediment samples were extracted from the ground surface to the base of the Pleistocene Terrace by Dr. Chris Moore, and were submitted for OSL dating using single aliquot analysis. This study provides new insight into the geochronology at Topper,
leading to an updated, if not complex chronology for the age of the pre Clovis deposits. The locations, methods employed, and initial results obtained from this analysis are presented in Appendix 5. Seven samples were taken from the Holocene Terrace deposits of a 4m x 4m unit along the East Wall of N263 E144. An additional five samples were taken from the three units of the Pleistocene Terrace excavation (N246 E138 West profile wall, N248 E140 North profile wall, and N243 E142 East profile wall).

The results of the OSL dating (Albert C. Goodyear, personal communication December 2014) confirm the prior radiocarbon analyses results that place the age of the Pleistocene Terrace as older than 50,000 cal yr B.P. However, the new dates place the age of the Pleistocene Sands and to a lesser degree the Pleistocene Terrace at an older age than previously had been shown. The two OSL samples taken from the Middle and Lower Pleistocene Terrace returned dates of 59,400 cal yr B.P. and 70,700 cal yr B.P., implying that the potential pre Clovis deposits are no older than the basal date. More interesting were the OSL results from the Pleistocene Sands which present a much older age for this depositional unit. Based on the single grain OSL analysis, the Pleistocene Sands range in age from 34,000 cal yr B.P. for the Upper alluvial sands associated with the top of unit 2b, to 62,000 cal yr B.P. at the contact with the Pleistocene Terrace. A third sample extracted from the middle of unit 2b returned a date of 53,800 cal yr B.P. Overall, these results indicate comparatively little time elapsed between the terminal accretion of low-energy floodplain Pleistocene Terrace deposits (59,400 cal yr B.P), and the onset of higher energy rapid deposition of the white Pleistocene Sands (62,000 cal yr B.P). By contrast, prior dates for the Pleistocene Sands deposits using the combined multiple and single aliquot method (Waters et al. 2009) were found to range in age from 14.0+–1.2ka B.P. to <37.2ka B.P. Foreman
(2002) returned a date of 15.2 cal B.P. for these same deposits using the multiple aliquot technique.

Although the OSL dates give similar age determinations for the Pleistocene Terrace, there are considerable differences between the two studies regarding the age of the Pleistocene Sands. One study, using both multiple and single aliquot techniques, produced a younger age range for the deposit, whereas a subsequent, more recent study employing only the single aliquot method produced a much older date range for the Pleistocene Sands. Future research may be necessary to resolve these differences and to determine the age of the Pleistocene Sands at Topper.

**Paleoenvironment**

The lithic outcropping at Topper was a valuable commodity for Paleoindian hunter-gatherers, serving as a source of raw material for the production of stone tools. Along with this rich resource, Topper's environmental setting, located along the banks of the Savannah River, was likely significant in creating the extensive Paleoindian record at the site (Goodyear et al. 2007). As such, reconstructing the environment in which these early inhabitants lived is important for understanding resource procurement strategies inherent in Paleoindian life-ways. Plants provide a detailed record of the past, and researchers often use plant remains such as pollen, phytoliths, or charcoal as environmental proxies to examine change in the structure of climate, vegetation, and environmental parameter through time. Because researchers have noted that sudden environmental changes in the past might have had significant implications to human populations, it is important to provide the climate and paleoenvironmental context for the Topper Site and surrounding region to better understand the conditions under which past peoples may have lived.
**Late Pleistocene Climate Dynamics**

The Late Pleistocene is defined as the part of the Quaternary that began with the Last Glacial Maximum (21,000–18,000 cal yr B.P.) and encompasses the Last Glacial Interglacial Transition (LGIT), ca 14,500–12,200 cal yr B.P. (Hoek 2008:226) through 11,700 cal yr B.P., the beginning of the Holocene. In North America, deglaciation began at 18,000 cal yr B.P. and lasted until 6,000 cal yr B.P. (Gill 2009). In North America, the climate of the Late Glacial may be characterized as dynamic, fluctuating from periods of cold, dry, stabilized regimes, to those consisting of moderate but regionally unstable temperature and moisture patterns. These major climate changes are noted in the $^{18}$O/$^{16}$O oxygen isotope readings for temperature and moisture in Greenland ice cores. The Late Pleistocene period is further subdivided among a number of smaller intervals (stadials and interstadials) based upon world-wide abrupt oscillations in temperature. These include the Bølling (14,650–14,000 cal yr B.P.), the Older Dryas (14,000–13,700 cal yr B.P.), the Allerød (13,700–12,900 cal yr B.P.), and the Younger Dryas (12,900–11,700 cal yr B.P.) respectively (Anderson et al. 2015).

**Pollen Analysis and Reconstructing Vegetation change at the Topper Site**

Pollen is typically the most abundant plant remain preserved in Quaternary sediments, and as such the analysis of pollen grains is the principal technique used to reconstruct prehistoric environments (Birks and Birks 2004). Appendix 6 presents a discussion on the history of pollen research in the southeastern U.S. The results of pollen analysis may be used to form expectations about the paleovegetation history at the Topper Site in South Carolina.

A number of preliminary studies have documented the modern and prehistoric vegetation communities present in the areas surrounding the Topper Site. In 1985, John B. Nelson conducted an initial survey of the modern vegetation and found that four natural plant
communities are present within the site’s boundaries. Nelson identified a dry upland white oak, beech, and hickory community situated on the hilltop portion of the site; a hillslope community dominated by laurel oak; and a floodplain community along the oxbow of the Savannah River. A fourth less visible upland spring community may exist along the hilltop bluffs associated with various spring seepages. Most plants were found to be restricted to the wetland areas adjacent to the river. A full list of the plants identified by Nelson is provided in Table 3–3.

A study by Smallwood in 2008 attempted to recover plant microfossils from sediment samples collected from the upland contexts at the Topper Site to evaluate how they compare to the climatic sequences developed for the greater Southeast. Smallwood collected and analyzed four samples. A single sample was collected from underneath an artifact 10cmbs that served as a comparative control to represent the modern vegetation communities at the site (Smallwood n.d.). Three additional samples (2–4) were collected from “directly under Clovis artifacts lying flat in a buried archaeological component approximately 60 centimeters below surface” (Smallwood n.d.:8). Microscope slides from the four samples were analyzed, and the number of pollen grains for each type observed was counted. A Lycopodium tablet containing an average of 10,680 Lycopodium spores was added to the sample prior to observation to serve as a marker grain that permitted tabulation of pollen concentration values and functions as an indicator for unintended destruction of pollen during the lab protocol. Smallwood then considered the results relative to the number of observed Lycopodium spores in the sample (Smallwood n.d.).

The results of the analysis show that pollen is poorly preserved from the upland contexts at Topper, with pollen counts extremely low. According to Smallwood, the highest pollen concentration was obtained from sample 3 and contained a “mere 60.75 pollen grains per gram” (Smallwood n.d.:13). Based on this initial analysis of the identified pollen grains from the Clovis

deposits, oak was found to be the most predominant species from the upland contexts at Topper, occurring in all four samples examined. Hickory and pine were present in lesser abundances. Pollen was better “preserved in the modern sample collected at 10 centimeters below the surface” (Smallwood n.d.:13). Smallwood concluded that “pollen concentrations identified at Topper were far too minimal to make any direct conclusions”, and the samples examined were from only two locations within the sediment profile (Smallwood n.d.).

In addition to pollen, Smallwood identified a number of phytolith types. Accordingly, phytoliths were better preserved than the pollen at the site, and samples contained distinctive forms of grass phytoliths that retained cell shape after decay or burning of the organic tissue (Smallwood n.d.:14). Most types were identified as examples from the grass family (Gramineae). According to Smallwood, the Pleistocene-age samples also “have dumbbell-shaped phytoliths representing the Panicoid class of native tall grasses, and saddle-shaped Chloridoid phytoliths indicating short grasses” (Smallwood n.d.:14).

Smallwood’s study provides an initial depiction of the fossil pollen and phytolith records from the upland contexts at Topper. However, additional analyses were needed to determine if the same or similar patterns were present in the distribution of pollen from the Holocene Terrace portion of the Topper Site. Since soils types are different on each landform, the possibility exists that vegetation may differ as well. Therefore the present study conducted additional tests to reconstruct the paleovegetational history at the site. This study incorporated two separate analyses:

1. A microscopic examination of individual pollen grains collected from Holocene and Pleistocene sediment samples from a test unit on the Holocene and Pleistocene Terrace at Topper.
2. Pollen analysis of a sediment core recovered from the base of the alluvial terrace at Topper.

For the first study, two separate sediment samples were examined for fossil pollen. These samples were both collected from colluvial deposits within the Holocene and Pleistocene Terrace of the Savannah River and down-slope from the Hillside portion of the Topper Site. The first sample was collected from the Holocene sediments from the East profile wall of a 4m x 4m block excavation carried out in 2010 and 2011. The provenience for this sample is N263.01 E148.00 at an elevation of 98.86m (Figure A5–7). This elevation equates to the top of level three at 51cmbs and is beneath the plow zone. A single sediment sample was extracted from this location for examination. Slides were prepared and analyzed in the Laboratory of Paleoenvironmental Research at the University of Tennessee using a binocular compound microscope under a 400x magnification. Diagnostic pollen grains were counted by type. The results of the pollen analysis for this sample are presented in Table 3–4.

The pollen analysis of the Holocene sample indicates the presence of pollen from the sample. The majority of the pollen detected was oak (*Quercus*), with lesser occurrences of pine (*Pinus*) and hickory (*Carya*), suggesting a mixed deciduous forest at the time the pollen was deposited. The presence of water tupelo (*Nyssa aquatica*) indicates that wetland taxa were also present at the time of deposition. The second sediment sample was collected from directly under a biface preform of presumed Paleoindian age, artifact number 32, lying in a buried archaeological context at an elevation of 98.20m or 116cmbs, and from the provenience N263.46 E146.28. Pollen counts for this sample were very low, and most grains detected were incomplete or had torn exines, suggesting that conditions were poor for pollen preservation in this sandy context. Of the taxa identified, oak pollen (*Quercus*) was most common, with minor

occurrences of pine (*Pinus*). Hickory (*Carya*) only occurred in minute amounts, suggesting that conditions may have not been suitable for the widespread distribution of this species at the time.

Based on the available fossil pollen record at the site, Topper during the terminal Pleistocene probably consisted of an oak/hickory forest interspersed with stands of pine. These results largely corroborate Smallwood’s findings for the pollen sequence on the hillside portion of the Topper Site. It should be noted that pollen concentrations are far too low to make precise conclusions.

A second analysis was conducted to determine the preservation potential for fossil pollen from the Pleistocene Terrace at Topper. This analysis involved the examination of a sediment core obtained by Scott Harris using a vibracore starting at the base of the excavated Pleistocene Terrace at Topper of a surface unknown but of presumably great age, >60,000 B.P. The analytic protocol and results of this study are presented in detail in Appendix 7. The core was obtained from beneath the known cultural component at the site and the results are therefore best suited to simply provide an environmental reconstruction as opposed to the conditions under which a pre-Clovis population necessarily lived. Based on the palynological analysis of two slides, taxa associated with both cool and warm climate are represented consecutively (Table 3–5). The results indicate a pattern of general cooling recognized by the greater abundance of coniferous taxa (*Pinus* 7%, *Picea* 6%) compared to the older, deeper sample which was found to have a lower percentage of *Picea*. The results of this analysis potentially suggest show a change in vegetation at Topper during the Quaternary from temperate, moisture-thriving taxa, including a number of aquatic plant species, to that of boreal species that thrive in cooler environments. However, the samples are too similar to demonstrate this claim and require an examination of

additional pollen to make more robust interpretations about past climate at the site. Although no age brackets can as yet be conclusively assigned to this transition, based on the combined depth of the core and prior dating of the overlying sediments, both samples likely predate 60,000 years B.P. Future work should include the extraction and examination of sediment cores from the Holocene and Terminal Pleistocene deposits to gain a better understanding of the environment at the time of possible cultural occupation at the site. The chapter that follows provides the history of excavation at Topper.
The Topper Site (38AL23) was a prehistoric chert quarry located on a terrace of the Savannah River in Allendale County, South Carolina. Archaeological investigations at Topper beginning in 1985 and held continuously each summer from 1998–2012 have revealed evidence of a cultural sequence that covers 13,500 years of prehistory and potentially much more (Goodyear 2005a; Goodyear and Steffy 2003; Goodyear et al. 2007; Miller 2011). Excavations at Topper have primarily been carried out in two locations; a hilltop above the quarry where a dense Clovis occupation was discovered in 2004, and the alluvial terrace initially tested in 1985, and where potential evidence of a pre Clovis occupation overlain by Clovis and Holocene aged material culture was discovered in 1998. For the purpose of this study, the term alluvial terrace is employed to distinguish this area of the site from the hilltop excavation. Moreover, the term should not be confused with Pleistocene Terrace, which is used to describe a specific geological unit of the Alluvial terrace formation itself. The focus of this dissertation is on the materials recovered from the alluvial terrace. Figure 4–1 presents a map showing the ordinance and provenience location for all excavations on the alluvial terrace. Since 1984 a total of 392m² have been excavated in this area of the site resulting in the recovery and identification of 10,583 individually mapped artifacts (2.5cm in diameter or greater) weighing over 110kg., in addition to a substantial quantity of lithic materials from the 1/4 inch and 1/8 inch screen. Tables 4–1–2 present the number and distribution of mapped items by year and level for each unit excavated on the terrace. The present study examines a sample of the excavated units on the alluvial terrace, and as noted in chapter 1 includes 52m² of Holocene and Pleistocene Sands and 16m² of Pleistocene Terrace materials.

</table>
The provenience locations for the study sample are illustrated as highlighted boxes in Figure 4–1. In addition to the mapped artifacts, a sample of screened materials from 14 2m x 2m units from the ground surface to the top of the Pleistocene Terrace (elevation 97.05m) and 16 1m x 1m units from the top of the Pleistocene Terrace to its base at 95.25m have been examined in the present study. This sample includes well over 600,000g of quartz pebbles, cortical pebbles, debris, and flake debris, and is the focus of the analyses in the following chapters. The incidence of these materials recovered from the screen, by count and/or weight, is presented in Appendix 41. In the section that follows the excavation protocol at the site and results of excavation for each field season are briefly summarized, with a more detailed site history presented in Appendix 8.

The Topper Site was first discovered in 1971 and archaeological investigations were briefly carried out in 1984–1986 as part of a survey to locate prehistoric chert quarries in western Allendale County (Goodyear and Charles 1984:80–93). From 1998 through 2012 the site was extensively excavated as part of the Allendale Paleoindian expedition and since 2005 the site has been investigated through the Southeastern Paleoamerican Survey (SEPAS), an organization whose purpose is to support scientific research and to advance archaeological knowledge and carry out archaeological projects through the involvement of members of the public. Dr. Albert C. Goodyear has been the principal Investigator for the Topper project and has made or overseen all archaeological decisions with regard to the placement and method of excavations. From 2005 to 2012, Tom Pertierra, founder of SEPAS, held the role of logistics coordinator. In this role, Pertierra oversaw the day-to-day operations at the site and provided equipment necessary for excavation, analysis, and material transport. Scientific protocol on a day–to–day basis was overseen by the Senior Science Supervisor, who was in charge of all excavation in the absence of
Dr. Goodyear. From 1998–2004, Kenn Steffy held the position of Senior Science Supervisor at Topper, and oversaw all excavation on the Holocene and Pleistocene Terrace. After 2004, the role of Senior Science Supervisor was held by graduate students. Three individuals, Shane Miller (2006–2008), Ashley Smallwood (2009–2010), and Derek Anderson (2010–2012) have held the position of Senior Science Supervisor, and have been in charge of overseeing all facets of excavation on the hilltop and hillside areas of Topper. In addition to these positions, undergraduate and graduate students have been assigned as individual unit supervisors since 2005. Prior to this date, unit supervisors were both avocationalists and professional archaeologists. A list of all unit supervisors by year is presented in appendix 21. From 2005–2012, Douglas A. Sain supervised all work conducted on the Holocene and Pleistocene Terrace excavations at the site, including excavations into the pre Clovis deposits.

Excavations at Topper from 1998–2012 were conducted using a consistent series of procedures. The Holocene deposits on the Hilltop and Terrace were excavated in 2m x 2m units in 10cm arbitrary levels to a depth of 60cmbs, unless Paleoindian deposits were encountered first. Below 60cmbs units were excavated with trowels in 1m x 1m unit quads at 5cm intervals until two successive sterile levels, devoid of flakes, were encountered. All Pleistocene Sands and Terrace sediments were excavated in 1m x 1m units in 5cm arbitrary levels. During excavation, all sediment was recovered and water screened through 1/4 inch screen mesh to a depth of 60cmbs, and 1/8 inch screen mesh below 60cmbs. All materials recovered from the screen were subsequently bagged and assigned a corresponding level number. All items encountered that were 2.5 cm in diameter or greater were left in situ to be mapped, (three dimensionally piece plotted), and the unit was photographed prior to and after the mapping and removal of artifacts. All artifacts were removed only after having been properly recorded and photographed. Plotted
materials subsequently assigned artifact numbers and were bagged separately from the screened materials. Because the weight by size grade of all recovered artifacts and screen materials was recorded, it is possible to evaluate the percentage of materials that were missed in the field and subsequently ended up in the screen. Appendix 13 presents these data; as documented below, few such artifacts were missed over the course of the excavations from the pre Clovis excavation proveniences.

In addition to the excavation protocol, a backhoe was also used occasionally to test for the presence of cultural materials, and to examine the geostratigraphy of the site. As of 2012, a total of 20 backhoe trenches (BHT) have been excavated at Topper. Figure 4–2 presents the location of all backhoe trenches relative to unit excavation through the 2005 field season. A list of all Backhoe Trenches is provided in Appendix 14. The majority of the trenches were excavated in 1999 and 2000 in conjunction with the geoarchaeological investigations by Waters et al. (2009) to investigate the stratigraphic profile of the Pleistocene deposits at the site and to obtain materials suitable for radiometric or OSL dating. No backhoe trenches have been excavated since 2005. A total of 18 of the 20 backhoe trenches were excavated on the alluvial terrace, while the remaining two trenches were situated on the Hillside and Hilltop respectively. When backhoe trenches were opened, a small sample of fill from each trench was screened through 1/4 inch mesh.

Another issue concerning site recovery protocol involves the percentage rate of interobserver error in artifact recovery. According to procedure, all items 2.5cm or greater are three dimensionally mapped within the site grid. If items smaller than 2.5 cm were deemed to be of cultural origin or appear to take the form of chipped stone debris, such materials were also mapped. However, the potential exists that some items that meet this size criterion (>2.5cm)
Figure 4–2
Location of Backhoe Trenches (BHT) at Topper Site relative to Excavation Units. A total of 20 Backhoe Trenches have been excavated between 1984–2012.
were missed in the field and subsequently placed in the screen. To determine the rate of error in the mapping protocol, and to ascertain if the spatial array of artifacts has been preserved, all materials from the screen were subjected to a size grade analysis. Accordingly, the combined weight of all screened and plotted items greater than 2.5cm was recorded for each level, the total for which comprises 100% of the materials per level for the given size grade. By comparing the percentage of 2.5inch artifact screen weight to the percentage of 2.5 inch plotted artifact weight, it was possible to determine the error/artifact recovery rate for each level by stratigraphic deposit. The results of this analysis are presented in Appendix 13 and in Table 4–3. Based on the analysis, the average percentage of flaking debris greater than 2.5cm that was missed in the field ranges from a high of 8.6% for the Clovis deposits to a low of 4.1% for the Pleistocene Terrace. On average, 4.9% of chipped stone tools and debris from the Pleistocene Sands were missed and not mapped in the field. These findings imply that at least a small portion of the larger artifacts from the site were not mapped. Although the percentages are not high, the presence of screened artifacts larger than 2.5 cm illustrates one shortcoming of the current method.

Unless otherwise noted, a comprehensive analysis of the lithic materials recovered from these units other than those in the present sample have not been undertaken. The data presented has been tabulated directly from the unit level and feature forms. While the distribution of three-dimensionally mapped items from each unit is available, data pertaining to the bulk 1/4 and 1/8 inch screen materials have been inconsistently reported on the level records.

1998 Excavations

In May 1998 excavations at the Topper Site resumed after a 13-year hiatus. Eight 2m x 2m test units were excavated (N244 E106 – N244 E130) in 10cm arbitrary levels to 70cm in

depth with 5cm arbitrary levels commencing at depths below 70cm. A map of the 1998 excavations is presented in Figure 4–3. The 1998 excavations include a series of 5 2m x 2m units oriented along the N244 grid line from E106–E130, and three additional test units to the north along the N250, N254, and N282 gridlines. Figure 4–4 shows the 1998 test units undergoing excavation. The 1998 investigations resulted in the discovery of an abundance of lithic material of Archaic and probable Clovis age from the manufacture of chipped stone tools. A list of the recovered mapped items by type for the 1998 field excavation is provided in Tables A15–1 and A15–2. A Woodland component was also identified based on the presence of Refuge and Deptford pottery.

Prior to 1998, all excavations at Topper had ceased at sterile sediment at the base of the Paleoindian or Clovis levels (110cmbs). However, due to reports of “pre Clovis” discoveries at a number of sites (notably Cactus Hill, Virginia; Monte Verde, Chile; and Meadowcroft Rockshelter, Pennsylvania), Goodyear decided to take each excavation unit deeper to evaluate whether a pre Clovis occupation was present at Topper. Approximately 1 meter of sterile sediment was excavated by trowel in 5cm incremental levels beneath the Paleoindian levels in each of the eight 2m x 2m units. At two meters below the surface in unit N244 E130, Goodyear encountered a presumably cultural component consisting of what he described as a smashed core technology (Goodyear 2005). Possible artifacts recovered from these deposits included small prismatic blades, microlithic flake tools, cores, and debitage from the manufacture of these items. Examples of debitage recovered from the pre Clovis deposits of unit N244 E130 are presented in Figure 4–5. The pre Clovis items were recovered beneath stratigraphically intact deposits consisting of a Woodland Deptford ceramic zone from 10–20cmbs and a possible Paleoindian component consisting of utilized flakes, unifaces, and endscrapers from 70–80cmbs.

Examples of chert bend breaks (a,c), flake fragment (b) and small blades (d) recovered from the screen of the Pleistocene Sands deposits from units N244 E130 and N244 E118 at the Topper Site in 1998 (at bottom).
Figure 4–6 shows an *in situ* chert core from the pre Clovis deposits at 160cmbs in unit N244 E130.

One of the most common artifact types recovered from the pre Clovis deposits in 1998 was what Goodyear identified as a bend fracture or bend break flake. Bend breaks are flakes that are broken on an anvil that result in hard, burin-like edges and tips (Crabtree 1977; Cotterell and Kamminga 1987; Jennings 2011; Titmus and Woods 1986). An example of a bend break reproduction is presented in Figure 4–7 alongside an example recovered from the pre Clovis Pleistocene deposits at Topper. Bend breaks usually exhibit a lip on one face of the break indicating they are broken (snapped) and not struck by way of conventional percussive techniques. They are known to occur in North American Clovis and Folsom assemblages as a minor component in the flake tool assemblages, although skeptics (e.g. Morrow et al. 2012) argue that such flakes can also occur by natural processes or incidental breakage as well. Using experimental archaeology, Jennings (2011) compared the attributes of bend breaks from an experimental assemblage resulting from trampling to an assemblage of replicated examples to determine if bend breaks were intentionally produced to serve as tool edges, or were broken incidentally. Jennings found significant differences in the break types produced when the trampling assemblage was compared with the flakes that were intentionally fractured. The results of this study are discussed in detail, together with an analysis of similar materials from Topper, in chapters 7 and 8.

In addition to bend breaks, other artifacts and artifact associations of potential pre Clovis origin were identified at Topper in 1998 including chert scrapers, blades, utilized flakes, and boulder cores. The lithic items from pre Clovis contexts were most frequently recovered in

association with concentrated clusters of large lithic debris that have been described as possible anvil stones.

One lithic concentration labeled as Feature 23 from the Southeast corner of unit N244 E130 included two battered quartz pebbles, a core fragment, and three modified flake fragments. Figure 4–8 is a photograph of Feature 23, upon discovery, some of the feature continued into the adjoining unit and was subsequently excavated the following field season (see also Appendix 18, and Figures A18–2 and A18–3). These “pre Clovis” materials were recovered nearly one meter below the Clovis zone at the site. While no diagnostic artifacts associated with any known prehistoric culture from the region were identified within the reported pre Clovis deposits at Topper in 1998, the technological attributes present on many of the flakes (i.e., bulb of force, bulbar scar, platform remnant) suggested to the excavator that they were likely formed by cultural rather than natural processes (Goodyear 2000). However, skeptics of the proposition that these items are cultural in origin have argued that the proposed “pre Clovis” assemblage at Topper may result from natural processes such as thermal fracturing, or through “physical fracturing resulting from stream flow” (Waters et al. 2009:1309). Stratigraphically, the pre Clovis materials were recovered below a “moderately well-developed Bw paleosol horizon that formed in colluvial deposits” that lies beneath the Clovis cultural levels (Waters et al. 2009:1308). Optically Stimulated Luminescence (OSL) Dates obtained from the top of the proposed “pre Clovis” deposits returned dates of 15,200 year B.P. and 14,400 year B.P. respectively, suggesting a minimum age for the assemblage (Waters et al. 2009:1303–1308).

1999 Excavations

Excavations into the pre Clovis deposits on the terrace at Topper continued in 1999. Investigations were expanded to include the excavation of 60 square meters of Holocene and 32
Figure 4–8
Lithic Cluster from pre Clovis deposits at Topper (at top): N244 E140 South Wall 180cmbs (97.05–96.95m) 28 May, 1998. (Image courtesy Albert C. Goodyear).
square meters of Pleistocene-age sediments from a large block excavation (Goodyear 1999). Units opened in 1999 included a 48 square meter block extending from N208 along the East 130 line to N214 E136; a 4m x 2m block extending from N242 E130 to E132; and two 2m x 2m units along the northern perimeter of the site: N268 E132, and N282 E132 (Figure A22–2). As with previous seasons of fieldwork at Topper, cultural materials spanning the Paleoindian through Mississippian periods were identified from the deposits. A Paleoindian horizon was identified from 90–110cmbs in the 48 square meter primary block excavation (Goodyear 1999:9). Excavations into the pre Clovis levels at Topper in 1999 were conducted with a goal to establish the absolute depth of the archaeological component at the site. As such, each unit from the 48 square meter primary block was taken down to the top of the alluvial terrace at a depth of 220cmbs. At 150cmbs, microlithic artifacts were encountered similar in form to the ones identified in 1998.

The 1999 excavation produced many fewer and much smaller lithic items in this area of the compared to what was recovered from the eight 2m x 2m units excavated the prior field season (Goodyear 1999:9). In 1999 many small lithic items and debitage of possible pre Clovis origin were recovered in the screen as opposed to being mapped in situ. Moreover, because of the small nature of the items recovered, investigators could not rule out the possibility that these items had been “fluvially transported from their location of origin” (Goodyear 1999:9).

Excavation into a gray silty-clay terrace below 250cmbs in depth in the 48 square meter block continued to produce artifacts described as small flakes and utilized tools. These artifacts differed in morphology from items recovered from units excavated to the north at the base of the hill slope the prior field season. According to Goodyear, the artifacts from the Terrace may have been reworked into the deeper deposits as a result of bioturbation (Goodyear 2000:9).
In 1999, a team of geoscientists visited the Topper Site to obtain sediment samples in an attempt to reliably date the possible pre Clovis component. The team collected sediment samples for radiocarbon dating of humic acids (n=4) and Optically Stimulated Luminescence dating (Goodyear 2000:10). Two of the radiocarbon samples were taken from fluvial layers above and below the pre Clovis zone and returned dates of 6,670 ± 70 $^{14}$C yr B.P. and 8,270 ± 60 $^{14}$C yr B.P. respectively (Goodyear 2000). However, the units from which the sediment samples were collected are in the “zone of high ground-water flow” and are thus “clearly contaminated by more recent humic acids” (Goodyear 1999:10). The remaining two samples were taken from “discrete alluvial layers” that lie immediately below the terrace and produced dates of 20,860±90 $^{14}$C yr B.P. and 19,280 ± 140 $^{14}$C yr B.P. (Goodyear 1999:10).

In addition to the radiocarbon samples, four OSL samples were taken: three samples were obtained from the gray silty gray Pleistocene Terrace and a fourth was taken from the hilltop. Lab results provide three dates for the terrace unit and are 31,000 ± 4000 cal yr B.P., 35,000 ± 3,000 cal yr B.P. and 37,200 ± 3300 cal yr B.P. These dates are considered to reflect maximum ages for the deposits in this unit, and may be as much as 15,000 years too old (Goodyear 1999:11). According to the Geoscience team, the dates more likely reflect ages of 16,000, 20,000, and 22,000 cal yr B.P. respectively. The fourth OSL sample from eolian sands on the Topper Hillside returned a date of 40,000 cal yr B.P.

In addition to the 48 square meter block excavation, at least three additional subsurface investigations were carried out in 1999. One of these excavations was undertaken adjacent to where the initial pre Clovis discovery was made in 1998. A 4m x 2m block was excavated to a depth of 170cmbs in units N242 E130 and N242 E132. At least two distinct lithic working surfaces were identified and include an Archaic biface cache (labeled as F48) situated between...
98.30–98.40m (Figure A23–1, A24–1) and a linear distribution of lithic artifacts and debris situated at the base of the Pleistocene Sands from elevation of 96.90–97.05m. In the Pleistocene Sands of unit N242 E132, a pre Clovis lithic cluster (labeled as F 49) was observed in close proximity to Feature 23, which had been identified the prior field season. A plan-view of this unit and associated Feature 49 is presented in Figure A23–2. In addition to the 4m x 2m block excavation, two additional 2m x 2m units were excavated at the northern end of the Topper Site in 1999. These units include N268E132 and N282 E132. An examination of the contents of these units revealed fewer artifacts than were recovered from other areas of the site in 1999.

2000 Excavations

In May 2000, two new excavation blocks were opened at Topper. A 4m x 8m block was opened extending from N242 to N244 along the E128 to E136 gridlines, and a 2m x 4m block excavation opened along the N244 grid line from E146 to E150 (Goodyear 2000). A map showing the extent of the 2000 field excavations at Topper is presented in Figure A22–3. Both of these block excavations were situated to the north of the 1999 48 square meter block excavation illustrated at the bottom of Figure A22–2. The 4m x 8m block was an expansion of the 4m x 2m block that was originally excavated in 1999. Each of these units was excavated to the base of the Pleistocene Sands, at the contact with the Pleistocene Terrace. In the 4x8 block, excavation proceeded in 2m x 2m units in 10cm arbitrary levels to 100cmbs. At this depth excavation continued in 1m x 1m quads with 5cm levels, the same procedure conducted for prior block excavations however only that the transition to quads commenced at 100cmbs rather than 70cmbs. Figures A23–3 and A23–4 present the vertical distribution of artifacts from the 4m x 8m block excavation. An OSL sample from the base of the Holocene colluvium at 100cmbs (97.55m) returned a date of 13,000 to 14,000 cal yr B.P. (Goodyear 2000). This block excavation
lacked evidence for diagnostic Clovis artifacts. However, a “transversely flaked and basally-thinned biface blank” was recovered and was classified as Clovis in origin based on the associated date (Goodyear 2000:18). Excavation produced little evidence that flooding had disturbed the archaeological deposits, indicating that the “Savannah River had already down cut to its present base level” at some point prior to the time these materials were deposited (Goodyear 2000:22). Continued excavation in this block excavation below 100 cmbs revealed an absence of river-stained chert, a form of chert that was commonly exploited by the Clovis inhabitants of the site, and that has been inferred to have a different history than the upland chert that outcrops along the hillside.

In the 2m x 4m block, excavation commenced in 10 cm levels from the ground surface to the base of the Pleistocene Sands, terminating at the contact with the terrace at 220 cmbs (Goodyear 2000). The top 140 cm of sediments of this block were preliminarily identified as slopewash sands, while fine-textured pedogenic layers and lamellae were prominent at the base of the Pleistocene Sands (Goodyear 2000:19). The vertical distribution of mapped artifacts from the 2000 2m x 4m block excavation is presented in Figure A23–5. Very few formal tools were recovered from the Holocene deposits. However, excavations in this area indicate a substantial quantity of lithic materials came from the Pleistocene Sands. Most lithic artifacts recovered from the pre Clovis deposits in this block were preliminarily identified as flakes, debitage, or chert pebbles/cobbles and are discussed in greater detail in chapter 6.

Distinct clusters of chert cobbles and chipped stone debris were identified in two separate levels within the Pleistocene Sands. From 180–190cmbs, a circular cluster of cobbles was found in association with a number of chert cores and hammerstone fragments in the Southwest corner of unit N245 E149. This cluster was labeled Feature 67. Near the base of the excavation, a
second circular cluster of rocks and tested chert cobles was also identified in the extreme
northeast corner of unit N245 E147 at 200cmbs, and was designated Feature 68 (Figure A23–7).
At the base of the unit, concentrations of weathered chert boulders were encountered, similar in
form to the concentrations identified in the 4m x 8m block. Goodyear has proposed that these
boulders could be the original source of the reported pre–Clovis cultural deposits at the site
(Goodyear 2000). Due to time constraints at the end of the 2000 field season, lithic materials that
were partially excavated had to be left in situ resting on the terrace surface. The unit was
subsequently covered with plastic and backfilled.

2001 Excavations

In 2001 archaeological excavations at Topper were carried out in three separate areas,
resulting in the addition of 86 square meters of excavation to the site’s cumulative total (Figure
A22–4). The excavation blocks opened in 2001 include:
1. A 5m x 10m block opened up adjacent to the 4m x 8m block that was completed in 2000. This
block began at the N236 E127 gridlines and extended to the northeast corner of unit N242 E137
with a 1m baulk on the south, east and west margins of the excavation. The vertical distribution
of artifacts from the 5m x 10m block is presented in Figure A23–8.
2. A 4x6m block placed along the E102–106 grid line from N230–N240.
3. Ten 1x2m units that formed a U and served as a baulk for the 5x10 block excavation. These
units were placed on the southern, eastern and western margins of the 5x10m block (Figure A22–
4).

The 5m x 10m block excavation extended the coverage of the pre Clovis units by 32
contiguous square meters to the south of the 2000 block, and resulted in the discovery of
additional spatially clustered chert concentrations atop the alluvial terrace surface (Goodyear
In this case, removal of the 5m x 10m block was conducted using an alternative excavation strategy that differed from prior block excavations. Rather than removing sediments in arbitrary 10cm levels from ground surface, the top 70cm was strategically removed in two separate levels. Level one was a road surface with varying elevations, and was excavated through the base of the plow zone. Materials were screened for diagnostic artifacts, which were picked out of the screen in the field and the remaining non-diagnostic material collected in screen bags. Level two of the 5m x 10m block was excavated from the base of the plow zone to a depth of 70cmbs, and was screened for diagnostic artifacts in a similar fashion as the upper level above. These two levels contained diagnostic artifacts associated with both Woodland and Late Archaic cultures of the region. Artifacts were only mapped when encountered *in situ*. Subsequent excavation below level two commenced at 70cmbs (98.00m), and continued in 10cm arbitrary levels to the top of the Pleistocene Terrace at 96.60m.

All sediments below 98.00m were dry screened through 1/8 inch screen mesh and the screened materials were collected for future analysis. Materials below 97.20cm were water screened. As a result of the larger level size for the upper meter of excavation of the 5m x 10m block, the potential was significantly greater that *in situ* artifacts would be missed in original contexts and subsequently recovered from the screen.

Artifacts classified as cultural materials were found throughout the 5m x 10m block excavation in 2001. A profile map showing the distribution of plotted artifacts and associated features is presented in Figure A23–9. A significant Middle to Late Archaic (MALA) presence was identified from the base of level two and extending into level three from approximately 60–80cmbs (98.10–97.90m). Below this a Taylor occupation was identified. Dating to about 11,500 cal yr B.P. (Anderson and Sassaman 2012), Taylor points are a variety of Early Archaic side-
notched points that are commonly recovered across the Atlantic Coastal Plain of the Southeast. At Topper, the occurrence of such points suggests an occupational surface toward the bottom of Holocene-age colluvial slopewash sands that conforms to the slope of the present day ground surface. Post-dating Clovis by some 1500 years, the Taylor occupation at Topper represents the first substantial occupation after Clovis, although the 1985 recovery of a Suwannee point suggests a discernable Late Paleoindian occupation as well. Figure 4–9 presents the vertical distribution of Taylor points recovered from the Terrace excavation at Topper. Based on the spatial patterning of these points on a common surface within the site grid, the assemblage likely reflects an old stable surface based on the co-coccurrence of a Clovis point from the same approximate level. In addition to the Taylor assemblage, at least two distinct clusters of Paleoindian artifacts were identified and are presented on the plan-view map in Figure A23–9.

The results of the 2001 5m x 10m block pre Clovis excavation produced at least four lithic clusters (Figure A23–8). These clusters were subsequently given feature numbers and include Features 77, 80, 82, and 83. The pre Clovis features were well defined and typically consisted of numerous lithic items that, under preliminary observation, exhibit attributes consistent with chipped stone debris (Goodyear 2001). A description of the potential pre Clovis tool assemblage recovered from this block excavation is presented in Appendix 8.

Apart from the 5m x 10m block excavation, two additional block excavations were opened in 2001. Excavations were conducted along the southern, eastern, and western perimeter of the 5x10m block excavation and served as a baulk that would prevent collapse of the sandy
Figure 4–9

profile wall as excavation progressed deeper. In total, ten 1m x 2m units were placed and were excavated to a depth of 97.80m (approximately 110cmbd) to the base of the Clovis deposits. To the west of the 1m x 2m units, a 4m x 6m block was excavated to 97.00m or 113cmbd, the base of the Clovis zone. Excavation below the Clovis zone was not undertaken in this block. The interpretation that this area served as a lithic workstation is based primarily on the diversity of tool forms and associated manufacture debris recovered in close proximity (Figure A23–10).

In addition to the block excavations, geoarchaeological research at Topper in 2001 was undertaken to date the pre Clovis deposits at the site with greater precision. One problematic issue compounding the dating of these deposits was the general lack of organic material suitable for radiocarbon dating from the pre Clovis zone (Goodyear 2001). In 2001 a sample of organic carbon was recovered from the base of the Pleistocene Terrace at 4.25 meters below surface from the base of BHT 14, which was excavated in Units N244 E130 and N244 E132. The organic material was submitted for analysis, and returned a calibrated date of 45,700 cal yr B.P. (CAMS–78602). Because this date falls at the extreme range of the ability of radiocarbon dating, the date is in all likelihood radiocarbon dead and thus provides a minimum date for the Pleistocene Terrace (Goodyear 2001:19). In addition to this date, BHT 14 also provided remarkably well preserved plant remains from a “black gumbo clay” encountered at 5m below ground surface (Goodyear 2001:20). Samples of this material were collected for examination. Materials observed from this clay by Dorothy Peteet were found to include hickory nuts, grasses, and pine needles, among other macrobotanicals (Peteet n.d.). Similar materials were recovered from the base of BHT 17 from a vibracore in 2012. Two samples of macrofossils collected from the
Figure 4–10
Possible pre Clovis flake tools from the 2002–2012 5m x 9m block excavation from the Topper Site (38AL23).
Pleistocene Terrace were dated by Tom Stafford and returned 14C dates of >54,000 and >55,000 yr B.P. indicating that they were C14 dead (Goodyear 2001:20).

**2002 Excavations**

The goal of the 2002 field season was to gather additional excavated materials from the pre Clovis zone near the 5m x 10m block, and to expand the search for evidence of Clovis materials along the northern perimeter of the site (Goodyear 2003). The location of the 2002 field excavations at Topper are presented in Figure A22–5. During the field season a new 5m x 9m block excavation was opened up immediately to the east of the 2000 4m x 8m block. This excavation was situated along the N242–N246 and E136–E144 gridlines, and was taken to the top of the Pleistocene terrace at 97.35m. The top 70cm of sediments were excavated in two levels. The first level included the plowzone (0–20cmbs) while level two extended from 20–70cmbs and included Mississippian, Woodland, and Middle to Late Archaic period cultural materials. While materials were screened in 1/4inch screen mesh, only a representative sample of the general screen materials was saved. These materials were excluded from the study sample.

The results of the 5m x 9m block investigation revealed a minor Woodland and Mississippian component, a substantial Middle to Late Archaic component from 35–50cmbs dominated by numerous hafted bifaces, a Paleoindian component approximately 1 meter below the ground surface consisting of numerous unifacial and non-diagnostic bifacial tools from Pleistocene-age sediments, and a possible pre Clovis assemblage stratigraphically separated from the Paleoindian deposits and consisting of spatially clustered concentrations of chert cobbles and pebbles and associated flake tools within 25cm of the top of the Pleistocene Terrace. Figure 4–10 presents a sample of the flake tools recovered from the 2002 5m x 9m block excavation. The vertical distribution of artifacts from the 2002 5m x 9m block excavation is
presented in Figure A23–11, and shows two distinct deposits (the Holocene and Clovis deposits, and an underlying pre Clovis assemblage) separated by archaeologically sterile sediments. The distribution of mapped artifacts from the 2002 5m x 9m block excavation is presented in Appendix 15.

The pre Clovis deposits from the 5m x 9m block excavation are characterized as spatially clustered associations of chert cobbles, cores, and microlithic tools including small blades, flake tools and bend breaks. A sample of the pre Clovis tools are presented in Figures A35–4 through 12. The lack of bifaces distinguishes the pre Clovis zone from the overlying Clovis and Archaic materials. The pre Clovis lithic deposits in this area of the site range in depth from 97.75m to 97.10m, the contact with the Pleistocene Terrace. However, by the completion of the 2002 field season, excavation in the 5m x 9m block had only reached within 15cm of the top of the Pleistocene Terrace surface.

Apart from the 5m x 9m block excavation, a substantial Clovis lithic workstation was also encountered in two separate excavation blocks in 2002: one occurring in N267–271 and E134–138, and a second from N 284–N288 and E134–140 (Figure A22–5). The Clovis artifacts were identified based on the co-occurrence of outré passé flakes recovered in association with the base of a single fluted point. As such, the lithic deposits were interpreted as a Clovis workstation where biface and blades were produced and subsequently discarded after use.

In the N267–271 and E134–138 2002 block, excavation below the Clovis zone commenced as a 2m x 2m unit (N267 E135) to the top of the Pleistocene Terrace. The purpose of this excavation was to test the proposition that a pre Clovis occupation was present north of the primary 5m x 9m block excavation, and upstream from all other identified materials of such age (Goodyear 2003). Four square meters of sediments were excavated down to the Pleistocene
Terrace, with little evidence for artifact-bearing deposits below the Clovis levels, contrasting markedly with the high artifact densities encountered in the primary block excavation ca. 20 m to the south.

In 2002, the Topper Site was visited again by a team of geologists led by Mike Waters, John Foss and Tom Stafford. A backhoe trench was excavated to help “clarify” if a potential weathered “red” terrace remnant identified the previous field season at the northern end of the site was related to the Pleistocene Terrace (Goodyear 2003:25). This trench, labeled BHT 15, was placed along the N284 gridline and proceeded 50m up the hillslope to an elevation of 103m. The results of the geoarchaeological investigation for this season revealed that the weathered Terrace remnant (Figure 4–11) was a paleosol that “separated the Holocene colluvium” from the underlying Pleistocene alluvial sediments (Goodyear 2003:25). John Foss, soil morphologist, concluded that the weathered paleosol in this location had taken 2,000 to 4,000 years to form (Goodyear 2003:25). Toward the southern end of BHT15 the paleosol decreases in thickness, eventually terminating where the Holocene colluvial sediments rest atop Pleistocene white sands.

The excavation of BHT15 revealed a significant Clovis presence at the bottom of the Holocene colluvium. Artifacts identified from this trench include early stage prismatic blades, blade core preparation flakes, and outré passé flakes. The majority of the artifacts encountered from BHT 15 appear to reflect early stages of the lithic reduction continuum. Therefore this region of the site was interpreted as a chert processing center where lithic materials were roughed out from the adjacent chert quarry and initially reduced to manageable forms.

**2003 Excavations**

Excavations at Topper in 2003 centered on three specific tasks: the completion of the 2002 5m x 9m block to the Terrace surface, the opening of a 6m x 6m block excavation, and a series of five 2m x 2m units along the northern perimeter of the site. The locations of these excavations are highlighted on the map in Figure A22–5. The provenience and artifact classification for all mapped and screen artifacts recovered during the 2003 field season are presented in Appendix 15 and in Tables A15–10 and A15–11.

In 2003, excavation continued in four of the 2m x 2m units from the 5m x 9m block excavation begun the prior year. These units were N242 E140, N242 E142, N244 E140, and N244 E142. In these units excavations centered on the removal of the remaining 20cm (in four 5cm levels) of Pleistocene Sands to the contact with the Terrace. Of note, six chert tools were recovered from these units, and at least two were found in close proximity to a large chert boulder resting at the contact of the Pleistocene Terrace. These items, according to Goodyear (2005), are irrefutable evidence of human agency. A single feature was identified in 2003, a lithic cluster designated Feature 90 and composed of chert cobbles, flakes, a utilized flake, cores, a single bend break, and a quartz hammerstone fragment. Feature 90 was encountered near the contact with the Pleistocene Terrace surface at elevation 97.30–97.25m. A profile and plan view map of the 2003 5m x 9m excavation shows the spatial distribution of mapped artifacts associated with Feature 90 (Figure A23–13). In addition to Feature 90, a second lithic cluster was encountered in unit N244 E142 between 97.30–97.25m that was not assigned a feature number. Two of the chert flakes associated with this lithic cluster were found to refit to scars on the surface of the adjacent boulder classified as an anvil (Figure 4–12).

At the conclusion of the 2003 5m x 9m block excavation, chert artifacts and lithic concentrations were observed embedded in the top of the unexcavated Pleistocene Terrace at approximately 97.05m (Goodyear 2005). Consequently, a backhoe trench (BHT 17) was excavated into this terrace at the base of the 5m x 9m block in July of 2003 (Appendix 14). Prior to the excavation of this trench, the terrace surface was prepared by removing the uppermost 50cm of sediment using conventional excavation methods. Units prepared for the backhoe trench excavation include N242/N245 to E140/E143 in 1m x 1m units. The fill recovered from this excavation were water screened using 1/8 inch mesh. BHT17 was subsequently excavated in two levels from ca. 97.00–96.60m, and from ca. 96.60–95.65m. The footprint for these excavations extended from N243 to N245 along the North gridline and from E140 to E143 along the East gridline. A profile map of BHT 17 is shown in Figure A14–5. As excavation proceeded, all sediments and their contents were collected and each level was screened separately. When lithic items were encountered they were mapped using a transit and stadia rod (Goodyear 2005:9). However, most items were recovered from the screen. The distribution of lithic items recovered from BHT 17 is presented in Appendix 15. The materials recovered from this excavation yielded additional chipped stone debris. Goodyear asserted that these materials exhibit lithic attributes consistent with human agency (Goodyear 2005).

In addition to the 5m x 9m block excavation, a new 6m x 6m block excavation was opened in 2003 and along the N270 E152 grid line to N276 E158. The goal of this excavation, along with another block 16m to the north, was to determine if there are similar patterns in the distribution of pre Clovis materials along the northern perimeter of the site. In the block, excavation began at ground surface (ca. 99.30m) and continued to the base of the Clovis deposits. Clovis artifacts encountered in this block are interpreted, based on observation, to
represent early stage lithic reduction and core preparation, as the majority of lithic cobbles were relatively large and still retain cortex (Goodyear 2003). The natural source of this chert was identified by Goodyear (2005) as occurring up the hillslope 15 to 20 meters “where it had been exposed by erosion in previous millennia” (Goodyear 2005:6). In total, more than 700 individual lithic items were identified and recovered from the Paleoindian levels in this block, although the cortical pebbles and debris that was uncovered was simply collected and bagged by 1m squares rather than individually mapped. According to Goodyear, “due to the amount of time available and the dense nature of the deposit, this was the compromise solution for collecting all the material off the floor” (Goodyear 2005:4). As a result, a map of the artifacts recovered from this unit would be misleading given the quantity of piece plot data missing from Clovis deposits. An examination of the level records also failed to identify the precise number of artifacts recovered from the screen from this excavation. Figure 4–13 illustrates the dense occurrence of Clovis artifacts in the 2003 6m x 6m block excavation.

Immediately beneath the Clovis deposits, the excavation area was reduced to a 4m x 5m block (N272 E152 to N276 E157) and excavation continued through a “red” paleosol (Goodyear 2005:4). Other than quartz pebbles and “chemically weathered cortical material,” the paleosol was sterile of archaeological materials within the 20 square meters, indicating an absence of human occupation between the Clovis and reported pre Clovis assemblage from the Pleistocene Sands (Goodyear 2005:5). Below the paleosol, excavation continued as a 2m x 4m unit (N274 E154) from 98.25m through white Pleistocene-age alluvial sands to the top of the Pleistocene Terrace at 97.00m. From the Pleistocene Sands, small flakes were recovered, some of which had bend break fractures consistent with those found in the primary 5m x 9m block (N242–N246 and E136–E144) excavated to the south in 2002–2003. At the conclusion of excavation, a backhoe
Figure 4–13
Distribution of Clovis artifacts from 2003 6m x 6m block excavation at the Topper Site. (Image courtesy Albert C. Goodyear).
trench (BHT16) was excavated along the southern terminus of the block so that the profile of the units could be drawn and examined in greater detail.

To the north of the 6m x 6m block excavation, a third excavation centered on expanding the 2002 N284–E134 block (Figure A23–7). Five 2m x 2m units were placed extending from N284 E132 to N288 E136. Excavation began at 98.50m and concluded at the base of the Holocene Colluvium at 97.30m. Excavation commenced in 10cm arbitrary levels to a depth of 97.90m and materials were screened using 1/4 inch mesh. At 97.90m, excavation was conducted in 5cm levels in quads, with all materials screened in 1/8 inch screen mesh. Cultural materials associated with Woodland and Archaic periods were recovered from the Holocene deposits. A possible Paleoindian assemblage was identified from the five 2m x 2m unit excavations. Although the base of a Clovis point was recovered from this area in 2002, no such items were recovered during the 2003 excavations.

**2004 Excavations**

In 2004 excavation on the Terrace at Topper was focused on three areas (Figure A22–8). These included: completing the 2002–2003 pre Clovis 5m x 9m block through the Pleistocene Sands to the top of the clay Pleistocene Terrace, and subsequent excavation of terrace sediments surrounding BHT 17; the excavation of a 4m x 8m block from N290 E132 to N292 E138; and the excavation of a series of eight-test units placed on the hillside slope where Clovis artifacts had been observed eroding from the base of a road bed. Because the results of the hillside excavations at Topper have been extensively documented and reported in a number of publications (Miller 2007; Smallwood 2010; 2012), the focus of this discussion will be on the excavation of the Pleistocene Sands and Terrace 5m x 9m block, where artifacts of potential pre Clovis origin had been documented in previous field seasons. However, a brief mention should
be made regarding the hillside and hilltop excavations as they are mapped on separate grid systems from the Terrace excavations. When excavations on the hillside were initiated in 2004, a new grid system was established. This was necessary, as at the time the hilltop portion of the site was still referred to in the site files as 38AL139. Over the course of the next three field seasons (2005–2007) at least three additional grid systems were established on the hillside. Each of these grid systems is highlighted on the map in Figure A22–9. The inclusion of multiple grid systems often led to complications in the recording, analysis, and comparison of spatial data regarding the site contents, since in some instances two or more units from different areas of the same site shared the same provenience grid number. With regard to the present study, when artifacts are presented in figures that derive from the hilltop or hillside, the provenience and grid system refer to that used when the artifacts were recovered.

The locations where excavations were carried out at Topper in 2004 are presented in Figures A22–8 and A22–9, and the distribution of the 2004 artifacts by tool type is presented in Appendix 15. Because of increased awareness in mapping protocol, fewer artifacts were recovered from the screen in 2004. This pattern continued through the 2012 field season, resulting in greater archaeological visibility for the site as a whole.

Initial excavations in 2004 centered on the excavation of partial and full 1m x 1m units surrounding the footprint of the exposed backhoe trench 17. During the first week of the field season a discrete lens of presumably charred material was observed within the exposed BHT and eroding from the margin near the base of excavation BHT17 (Figure 4–14). This lens was basin-shaped, was 50cm in width by 8cm in depth, and was located at 95.25m, 3 m below ground surface at grid coordinate N245.00 E141.00. This charred lens was designated Feature 91. Removal of a sediment sample from this lens resulted in the discovery of a single thermally
Figure 4–14
Feature 91 at the base of BHT 17. N245.00 E141. At left; Profile wall of BHT 17 above F91 where sediment samples were obtained. Top right: Presumed charred lens with associated chert flake in situ at 95.25m. Bottom right: Feature 91 bisected for analysis
altered chert flake fragment, recovered from within the charred sediment (Goodyear 2005) (Figure 4–15). A sample of the organic materials associated with Feature 91 was sent for radiocarbon dating and returned dates of 50,300 $^{14}$C yr B.P. (UCIAMS 11682) and 51,700 $^{14}$C yr B.P. (UCIAMS 11683) (Waters et al. 2009). Figure 4–16 illustrates a sediment sample from Feature 91 showing presumed charred materials in the sediment.

Sarah Sherwood, a geoarchaeologist from the University of Tennessee, was contacted to conduct a micromorphological analysis of samples from Feature 91. A goal of this study was to evaluate whether Feature 91 was a prehistoric hearth, or a natural deposit” (Sherwood and Goldberg 2006). If the feature was in fact a product of human agency then there should exist evidence for “charcoal or some other fuel that show evidence of burning, burned sediment, or micro-artifacts (Sherwood and Goldberg 2006:3). The analysis found that the reported lens was composed primarily of woody plant fragments that had undergone humification as opposed to burning (Sherwood and Goldberg 2006) (Figure 4–17). Furthermore, there was no evidence of micro-artifacts or indication that the sediment and surrounding matrix had been altered by heat. Therefore, apart from the isolated chert flake within the context of the humified lens, the results of this study offer no “evidence that the contents of Feature 91 were tied to human activity” or fire (Sherwood and Goldberg 2006:19).

With the discovery of artifacts of potential human agency within the Pleistocene Terrace, a 2004 controlled excavation was undertaken of the terrace sediments surrounding BHT 17. This excavation began at the top of the terrace at 97.35m. Three full (N242 E140 SE, N242 E140 SW, N242 E142 SW) and one partial (N242 E140 NE) 1m x 1m meter units were placed around the margins of the trench and within the grid system. A plan-view map of the terrace excavations from 2004–2012 is illustrated in Figure A22–12. Excavations in this area were taken

to 96.60m by the end of the 2004 field season. The mapped artifacts are presented in Table A15–13. Within these units, a cluster of lithic artifacts was mapped, the majority of items occurring between 96.90–96.80m (see Table A15–12 for an image of this cluster). These lithic items were pedestalled so as to gain a better perspective of the special integrity of the terrace deposits, but were not assigned a feature number. These artifacts were preliminarily identified as flakes, worked chert cobbles, bend break flakes, flake tools, cores, and weathered chert cobbles (Goodyear 2005:6).

In 2004 a 4m x 8m excavation block was opened at the northern perimeter of the site along the N290 and N292 gridlines and extended to the east along the E132 to E138 gridlines. This block served as an expansion to the north of the five 2m x 2m units that were opened during the 2002 and 2003 field season. Unit excavations began at 98.70m and were taken to a depth of 97.30m, at the base of the Pleistocene Sands. Very few Woodland and Archaic artifacts were recovered from this block as evidenced by the profile map in Figure A23–15. Similar to the discoveries in this area in 2002, a dense Clovis floor was uncovered that is approximately 20cm in thickness and “overlain by relatively sterile” Holocene deposits (Goodyear 2005:7). According to Goodyear (2005:7), the Clovis occupation in this area of the site represents “habitation life” as craft activities are often associated with a diverse range of tool forms including unifaces. Since 2002, a total of 70 square meters have been excavated at the northern perimeter of the site, and have produced “one complete Clovis point base and five Clovis preforms” as well as a diverse range of tool forms including unifaces, scrapers blades and utilized flakes (Goodyear 2005:8).
In 2005 excavations at Topper expanded with the formation of the Southeastern Paleoamerican Survey (SEPAS), and the hosting of a conference directed to presenting and evaluating the fieldwork to date (Goodyear 2014). One of the first objectives of SEPAS was the development and organization of a major archaeological conference held in Columbia, South Carolina, referred to as the Clovis in the Southeast Conference (Goodyear 2014). In October of 2005 the Topper Site was visited by archaeologists and members of the public who attended the conference. All excavation units from the Pleistocene Terrace excavation were prepared and exposed for display, and provided an opportunity for professionals, avocationalists, and members of the public to ask questions and discuss issues relevant to the potential pre Clovis occupation at the site.

Since 2005, excavations into the Pleistocene-age sediments at Topper have continued in four specific locations. These areas include excavations at the southern end of the Terrace surrounding BHT 17 from 2005–2009; excavations of Holocene and Pleistocene-aged sediments to the north of BHT17 from 2009–2012; excavations of the Pleistocene Sands in three 1m x 1m quads along the eastern margin of BHT17 in 2005 and 2011; and the excavation of Holocene and Pleistocene sediments from a 4m x 4m block 20m north of the primary pre Clovis excavation from 2010–2012. This latter excavation served as a control sample to test for the presence of pre Clovis outside of the initial 5m x 9m discovery location. The first three of the excavations described are presented in Figure A22–12 and the location of the fourth (4m x 4m block) is illustrated in Figure A22–10. In the sections that follow, the types of material culture and culture sequence encountered in these areas are provided for each field season.
2005–2009 Southern Pleistocene Terrace Excavation

The Southern Pleistocene Terrace excavation includes investigations conducted immediately adjacent to BHT17, where six 1m x 1m units and four partial units were placed along perimeter of the trench from 2005–2009 (Figure A22–12 highlighted in red). This area is an expansion and continuation of the Terrace units that were opened during the 2004 field season. These units were subsequently excavated to a depth of 95.35m by 2009. Goodyear (personal communication 2009) produced a profile map showing the spatial distribution of mapped artifacts in the units along the N242 E140–144 gridline, which he argues depicts three common surfaces or lithic manufacture zones within the Pleistocene Terrace (Figure 4–18).

This map is based on the vertical and horizontal spatial array of artifacts that Goodyear preliminarily identified in the field and lab. The analysis and ultimate classification of these artifacts was based primarily upon the presence or absence of detachment faces found on the piece plotted lithic materials. The present study reexamined these items in greater detail, and over a much larger sample, with analysis geared toward the observation of additional attribute states. The results are presented in Chapter 7.

In 2005 excavation at Topper centered on the controlled removal of sediments from partial units that had been impacted by the excavation of BHT17. An image showing ongoing excavation in partial units N242 E140 NW, N244 E140 SW, and N244 E140 SE during the 2005 field season is presented in Figure A25–25 and A25–26. Because these units were partial rather than full 1m x 1m units, excavation proceeded in 10cm levels rather than in the usual 5cm levels. The removal of these partial units was necessary to place BHT17 onto the site grid, and to allow for the expansion of additional terrace units to the south and east.
Figure 4–18
Profile map showing the spatial distribution of mapped artifacts from Pleistocene Terrace units N24E140SE, SW, and N22E142SW from 2004–2009. Profile viewing north (Image courtesy Albert C. Goodyear).
Near the base of the Pleistocene Terrace, the water table was encountered, requiring the continual removal of water from the excavation area with the aid of a pump. For excavation to proceed, it was necessary to pump water from the excavation area periodically and to trowel all contaminants from the excavation area before the resumption of field work. The fact that the deposits are frequently saturated implies that these postdepositional or taphonomic processes could have altered the stratigraphic integrity of the deposits. Numerous chert cobbles and boulders were encountered toward the base of the excavations, some of which appear to have flake removals from their surfaces. Most of the mapped items from these units consisted of cortical chert pebbles and debris (mapped items from these units are presented in Appendix 15). By the completion of the 2005 field season, all partial terrace units surrounding BHT17 had been excavated to 95.35m, arbitrarily classified as the base of the Pleistocene Terrace, as excavation into the deeper sediments was not possible owing to the encroachment of groundwater.

Excavation in three full 1m x 1m units, and one partial unit was carried out in the Pleistocene Terrace in 2006. These investigations include the continuation of excavation in the three full terrace 1m x 1m units started during the 2004 field season (N242E140 SE, N242E140 SW, N242E142 SW). Excavation in the E140 quads commenced at 96.80m and 96.60m respectively and were each taken down a total of 1m by the completion of the field season. Excavation in N242 E142 SW began at 96.80m and was taken down a total of 45cm by the season’s end. Excavation of one new partial unit, N242E142NW, was carried out beginning at 97.20m and terminating at 96.85m. The upper portions of the Pleistocene Terrace in these units consist of strong brown sandy clay oxidation stains. By the completion of the field season, excavation in the three full Pleistocene Terrace units had passed through these oxidation features
and into grey clayey sand. The transition between the oxidation stains and grey clay is highlighted in Figure A25–27.

Two artifacts of note were recovered from the Pleistocene Terrace deposits in 2006. A bend break with a graver spur was recovered from the west profile wall of N242 E140 SW (N242.68 E139.93) at a depth of 96.82 m, and a chert core was recovered from the same unit at a depth of 96.05 m. These artifacts are presented in Figure 4–19. Goodyear considers the core and bend break graver to be unequivocally the product of human agency. Moreover, the microscopic analysis of the bend break graver by Jim Wiederhold at Texas A&M found indications of use wear on this artifact. Although these artifacts occur within sediments that predate Clovis, one goal of the present study was to determine if they have been redeposited into the older sediments from the overlying deposits.

In 2006 it became apparent that a structure or shelter was necessary to protect the site from the elements. At the close of each field season, the excavation block was partially covered with plastic until work continued the following year. During the offseason BHT 17 would often fill with rainwater as a result of long-term exposure to the elements. Such conditions led to considerable cleanup efforts, and risks of contamination prior to the resumption of excavation the following season. As a remedy for this situation, a permanent shelter was constructed over the Pleistocene excavation in the spring of 2006.

The goal of the 2007 field season was to complete unit N242 E140 to the base of the Pleistocene Terrace, and to continue excavation in the west half of N242 E142. One new quad, N244 E138 SE was opened in 2007 and taken to a depth of 96.55 m by the completion of the field season. Towards the base of unit N242 E140 SE, a chert boulder with numerous detachment scars was uncovered (Figure A25–28). This boulder was exposed at the same general level where
Lithic core (top) and a graver on a bend break (below) recovered from 2006 Pleistocene Terrace excavation at the Topper Site (38AL23), Allendale County, S.C. Bend break graver recovered at N242.68 E139.93 96.82m. Core recovered from N242.86 E140.62 at 96.05m. (Images courtesy Albert C. Goodyear).
numerous lithic cobbles had been identified in 2005 at the base of the Pleistocene Terrace. Interestingly, an abundance of lithic items were recovered in the level associated with the base of this boulder. This association appears to be the byproduct of testing chert cobbles or core/anvil reduction. However, these detachments may also form as the result of natural formation processes such as lithic collision in a fluvial environment, or natural weathering. To establish which of these processes is more plausible is one focus of this dissertation. By the conclusion of the field season excavation in N242 E140 had brought these units to the arbitrary base of the Pleistocene Terrace at 95.35m.

In the 2008 field season, excavation continued in the west half of unit N242 E142. The research goals for 2008 season were to complete the N242 E142 quads to the base of the Pleistocene Terrace. One new quad was opened from the Pleistocene Terrace this season (N244E138 NE). By the completion of the 2008 field season, these units had been excavated to a depth of 95.90–96.00m respectively. A cluster of broken chert cobbles and what appear to be flake detachments were uncovered in the northwest quad of N242 E142 at a depth of 96.00m. This cluster was not assigned a feature number. Two of the lithic detachments from this cluster were found to refit to the cobbles in association, implying that post depositional disturbances have not altered the original position of these materials. Moreover, the location of the flake, which is positioned near the base of the cobble it refits, implies that it was likely removed by some means of force rather than by natural weathering. However, no markings that are indicative of applied force on the flake exterior or interior surfaces were identified. The results of a refit analysis are presented in greater detail in Chapter 7 and in Appendix 26.

The goal of the 2009 Topper terrace excavation was to complete all the units in the Pleistocene Terrace that had been opened over the two prior field seasons. These units included
the west half of N242 E142, and the northeast quad of N242 E138. Most artifacts preliminarily identified from the Pleistocene Terrace deposits of these levels are bend breaks, broken chert cobbles, chert flakes, and flake fragments. Due to a rise in the water table this season, excavation in these units was terminated at a depth of 95.45m. After the completion of the 2009 field season, excavation ceased in the area immediately surrounding the footprint of BHT 17.

**2005–2012 Northern Pleistocene Sands and Pleistocene Terrace Excavations**

The second location where fieldwork has been carried out since 2005 lies immediately to the north of BHT17, and includes units extending from N246 E136–E142 and N248 E 136–142 (Figure A22–12 highlighted in blue). This area is referred to as the Northern Terrace block. During the 2005 field season, excavation of the Northern Terrace block consisted of the systematic removal of the Holocene Sands to the top of the Pleistocene Terrace at 97.15m. This 4m x 6m block excavation revealed evidence of intact stratified archaeological deposits encompassing the Woodland through pre Clovis culture chronology.

A sediment analysis conducted by Alan West provided evidence for magnetic microspherules in immediate post-Clovis sediments obtained from the west profile wall of N248 E140 (Figure 4–20). These results, along with similar findings at nearly 50 additional site locations throughout the continental U.S., have been used as evidence for an impact event that may have led to the onset of the Younger Dryas ca. 12,900 cal yr B.P. (Bunch et al. 2012; Firestone et al. 2007; Israde-Alcantara et al. 2012; Kennett et al. 2009; Kenzie et al. 2014). However, this hypothesis has been met with criticism and debate continues as to whether or not such an event actually occurred (Gill et al. 2012; Holliday and Meltzer 2010; Meltzer et al. 2014; Pinter and Ishman 2008a, 2008b; Pinter et al. 2011a, 2011b; Surovell 2009).
The results of a sediment analysis to test for evidence of microspherules at the top of the Clovis levels in the west profile wall of N246 E140. There is a spike in iridium, nickel, manganese, and microspherules/magnetic particles at the Younger Dryas boundary (Image courtesy Firestone et al. 2007; West, n.d.).
A number of interesting discoveries were made at Topper during the 2005 field season in the Northern Terrace block excavation. In N248E142 at a depth of 97.40m, a pedogenic feature was identified below the Clovis horizon and was left in situ for further examination (Figure 4–21). This feature was described by Waters et al. (2009) as brown, silty sand that exhibits evidence of soil development. Lamellae (accumulations of oriented silicate clay on or bridging sand and silt grains) were visible throughout this feature, possibly indicating periods of enduring landform stability resulting in pedogenisis. This section soil formation is more compact than the overlying sand but is not as dense as the underlying clay Pleistocene Terrace, although clay particles are present within its structure. Because soils form during periods of long-term landform stability, it was thought that this feature could have developed at some point in time prior to the Clovis occupation at the site. Subsequent excavation in N246 E138 and N246 E140 revealed additional evidence of this soil formation. When encountered, the feature and associated sediment structure was pedestalled and left in place for further evaluation. In some instances, lithic materials including potential flakes and tools were observed embedded in the profile wall of the feature formation.

In 2007 David Leigh of the University of Georgia visited the site to examine the material structure of the pedogenic feature in an effort to better establish its age and origins. The original hypothesis was that this formation reflects pedogenesis, or a period of long-term landform stability and soil formation between the period of time that the river deposited alluvium at the site, and the period of initial Holocene colluvial deposition. If such processes were in fact occurring, then the feature likely formed during a period or periods of long-term landform stability and that as a consequence, the feature acts to extend or bolster the difference in age between the Clovis and proposed pre Clovis assemblages at the site. However, according to
Figure 4–21
Pedogenic feature in Unit N246 E142, as initially exposed in 2005 top of feature at 97.97.75m, base of feature at 97.20m.
Leigh (personal communication 2008), other processes could also be responsible for the occurrence of the pedogenic feature. The feature could reflect the translocation of illuvial clay particles out of the overlying Holocene colluvium and into the deposits below, forming an illuvial deposit. For example Mostafa (2011) found that the depth of clay deposition is thought to be controlled primarily by pore size. When pores become so small they can constrict water flow, as the pore is partially plugged by illuviated clays from prior episodes of translocation. In such case, it would be a stretch to use the pedogenic feature as an actual temporal marker for defining the extent of time elapsed between the termination of alluvial deposition onsite and the subsequent beginning of colluvial deposition. This is because the feature would not have formed between these two events, but primarily alongside the subsequent period of colluvial deposition.

Another possible explanation for the formation of the pedogenic feature is based largely on its proximity and relationship with the underlying clay terrace. Clay particles may not only have been redeposited by leaching from the Holocene deposits but may also have been translocated upward from the terrace itself. Although movement of clay particles through soil and sediments have typically been accepted as being predominantly a downward phenomenon, Mostafa and Burras (2011:34) suggest that the movement of clay in such matrix can be multidirectional. In such a scenario, the formation of the pedogenic feature would have been aided by the upward translocation of clay particles from the Terrace. A third possible explanation follows that the Pleistocene Terrace surface acts as an aquatard, prohibiting the downward movement of leached clay particles past the Pleistocene Sands/Pleistocene Terrace boundary. Upon reaching this point, clay particles build up over time resulting in a feature that resembles a buried soil. Remnants of this pedogenic feature have also been uncovered in units to the west in quads N246 E139 SE and SW. Locations where this soil formation is lacking may reflect areas
that have been scoured by the Savannah River during flood stages when the river flowed as a braided system. In March of 2012, John Foss took additional sediment samples from the pedogenic feature in an effort to conduct a geo-and micromorphological analysis. The results of this study are still pending.

In 2009 excavation into the Pleistocene Terrace resumed in the Northern Terrace block with the placement of nine 1m x 1m units immediately beneath the 2005 Holocene/Pleistocene Sands excavation (Figure A22–12 highlighted in blue). The goal of this excavation was to expand the areal extent of the existing 2005 block, and to determine if similar patterns exist in the distribution of artifacts preliminarily identified as bend fracture flakes from the Pleistocene Terrace. For excavation to proceed and for safety, it was necessary to construct a foot bridge above the existing BHT17. It was also necessary to expand the excavation block further to the north by the removal of a 2m baulk along the N248 and N250 gridlines. Thus additional Holocene sediments were excavated and contents collected as a result of this project.

In 2009 Megan King examined a suite of lithics and lithic debris recovered from six of the 1m x 1m meter terrace units from the Northern Terrace block as part of her MA thesis (King 2012). A map of these units is presented in Figure 6–1. King found evidence for conchoidal flakes from the contexts that underlie Clovis in this area of the site. The results of this study are examined in greater detail in chapter 5. Through the 2012 field season these six units, plus an additional three 1m x 1m units, have been taken to a depth of 96.50m, revealing additional lithic items of potential human agency. An image showing the extent of excavation in these nine 1m x 1m units through 2012 is presented in Figure A25–35. An examination of the number of mapped artifacts by type for the Northern Terrace excavation (Table A15–19) shows a similar incidence of bend break and flake tools from pre Clovis deposits.
2005 and 2011 Eastern Terrace Excavation

Beginning in 2005 excavation resumed in two 1m x 1m quads (N244 E144 SW, N242 E144NW) that had previously been excavated in 2002 and that originally served as the Eastern baulk for the primary 5m x 9m block excavation (Figure A22–12 highlighted in green). In 2002 the western half of these quads had been excavated to the base of the Holocene colluvium, forming a 1m x 2m block excavation. The goal of the 2005 field season was to carefully remove the Pleistocene sediments from these quads, extending to the contact with the clay Pleistocene Terrace. This entailed the removal of 13 5cm levels of sediments from a depth of 95.95m to 95.35m. Over the course of excavation, a total of 147 lithic items were mapped from these proveniences. The majority of items were classified as chert pebbles or chert flakes, although 10 artifacts were identified as chert tools from the pre Clovis Pleistocene Sands.

In 2011, excavation began on the eastern half of the 2005 1m x 2m block, starting at the ground surface and terminating at the top of the clay Pleistocene Terrace. The goal of this excavation was to expand the footprint of the exposed terrace surface to the east of BHT17. In total, 1302 items were three-dimensionally mapped revealing a dense lithic deposit in the locale. Most of these items were identified in the field as flakes, flake fragments, and chert pebbles. However, 161 items were classified as tools, the majority of which derive from the Clovis levels and from the base of the Pleistocene Sands. Artifacts recovered from Clovis contexts include utilized flakes, scrapers, and hammerstones. Items recovered from the Pleistocene Sands include bend breaks, utilized flakes, broken quartz pebbles and small blades. A single biface fragment was recovered but was not diagnostic. A single anvil stone was identified, resting at the contact with the Pleistocene Terrace, and was recovered in association with items classified as broken quartz pebbles and bend break flakes. No feature number was assigned to this lithic cluster.
**2010–2012 4 x 4m Block Excavation**

In March 2010, a 4m x 4m block excavation was placed 12m to the north of BHT 17 along the N262 grid line, and represents the third area where fieldwork on the Holocene and Pleistocene Terrace at Topper has been carried out since 2005. Figure A22–10 shows the location of the 2010 4m x 4m excavation. The goal of this excavation was to test whether artifacts of potential pre Clovis origin occur to the north, and further upstream from the primary 5m x 9m block excavation where such artifacts have been identified. An absence of pre Clovis artifacts from this 4m x 4m block would indicate that (a) the Savannah River had limited influence on the deposition of the Topper pre Clovis assemblage across the site, and (b) that the chert outcrop situated above the floodplain also had limited influence on the deposition and formation of the hypothesized pre Clovis assemblage through natural weathering, breakage and subsequent transport of materials down–slope.

The results of the 2010 4m x 4m block excavation yielded an extensive and dense Early Archaic and Paleoindian lithic floor near the base of the Holocene colluvium. The distributions of the artifacts recovered from this floor are given in Appendix 15. These items were composed largely of primary reduction debris. Of note was the recovery of a Taylor point, Taylor perform, and hafted end scraper (Figure 4–22). Possible Clovis artifacts consisted of weathered blades and unifaces, although no tools diagnostic to the Clovis period were recovered from this unit. An initial examination of the lithic items from these deposits indicates that they are probably related to early stage biface and core reduction (D. T. Anderson 2011).
Figure 4–22
Taylor preform (left) and Taylor point (right) recovered from 4m x 4m block excavation in 2010 (N262 E144). (Image courtesy of Derek Anderson).
To examine the integrity of deposits in the unit, a spatial analysis of the lithic assemblage was undertaken (D. T. Anderson 2011). For this analysis, all lithic items were classified into three categories based on cortex. Categories of cortex included upland cortex, river stained cortex, and river–stained chert. This analysis operated under the assumption that individual occupation areas can be identified based on the clustering of different cortex types. The results of this analysis showed that river–stained and river stained cortex flakes tend to cluster to the eastern half of the block whereas upland cortex flakes were clustered in the western half of the block (D. T. Anderson 2011). Moreover, the “correlation” of large flakes and cores typical of Clovis with items that have upland cortex suggest a possible Clovis occupation in the “lower half of the deposit” (D. T. Anderson 2011:18). The results of the spatial analysis revealed little evidence for disturbed areas within the profile (D. T. Anderson 2011). A subsequent refit analysis produced over 256 individual refits, comprising roughly 21.7% of the entire assemblage from the Paleoindian levels (D. T. Anderson 2010) (Figure A23–17).

Below the Paleoindian deposits, excavation proceeded as a 2m x 2m unit through the Pleistocene Sands to the top of the Pleistocene Terrace. These 70cm of sediments produced a total of 11 mapped items, and provided little evidence for clustered chert cobbles characteristic of the reported pre Clovis assemblage in the large excavation block to the south. A total of eight bend breaks and three flakes were recovered from this pre Clovis excavation. To provide additional insight on the age of the cultural sequence from the 2010 4m x 4m block excavation, 10 sediment samples were taken from the east profile wall of the unit and subsequently submitted for OSL dating. This analysis resulted in a chronology ranging from 17,500–19,400 cal yr B.P. for the Upper Pleistocene Sands (Units 2b, 2c). These subunits represent direct contributions of slope wash at the base of the hill after the Savannah River could no longer flood
at this elevation. Below this stratum, a date of 29,800 cal yr B.P. was obtained for the Lower Pleistocene Sands (Unit 2a) of the 4m x 4m block and may date a period when alluvium was being deposited at the site.

To date, a number of locations upstream and north from the primary block excavation have been excavated down to the Pleistocene Terrace. These excavations, illustrated in Figure A22–11, have revealed little evidence for nodules or clusters of chert and it is evident that such clusters only exist in the original 5m x 9m block excavation, which is also below the natural chert outcrop upslope. If the Topper pre Clovis assemblage was formed as the result of natural weathering and transport of lithic materials down-slope, then it follows that such materials should also be expected along the entirety of the base of the outcrop, and not in only one isolated locale such as where they have been recovered from the primary block excavation. The prospect that the pre Clovis assemblage is restricted to a single locale implies that neither the river, nor the weathering of the exposed chert outcrop were likely responsible for the formation of the entire hypothesized pre Clovis assemblage. Appendix 15 provides a list of all units (and mapped items) that have been excavated below Clovis that fall outside of the primary block excavation.

**Summary**

The excavations undertaken at the Topper Site and associated chert quarries since 1985 allow for the reconstruction of the culture history of the immediate vicinity. The Holocene cultural sequence at Topper is confined within what Waters et al. (2009:1303–1308) define as sub unit 3b and can be reconstructed based on the preceding geostratigraphic and archaeological research. The upper 30cm of sediment contains a “minor” Mississippian occupation (1100–1400 AD) and a considerable Middle and Late Woodland component (2500 B.P. to 1000 AD) consisting of pottery and triangular Yadkin lithic projectile points. From 40–50 cm is a Late
Archaic (4500 to 4000 cal yr B.P.) occupation consisting of stemmed projectile points and steatite fragments (Goodyear 2014). Just below the Late Archaic sediments at Topper, and ranging from 60–70 cmbs is an extraordinarily dense Allendale (MALA) component that is predominantly composed of heat–treated bifaces and point fragments (Figure A24–2). However, the earlier part of the Middle Archaic period at Topper is minor in scope and is characterized primarily by the occurrence of a small number of Morrow Mountain points (Figure A24–3). Apparently from about 7,500 to 6,000 cal yr B.P., there was an “abandonment of Topper as a quarry or habitation site” based on the general lack of artifacts recovered from sediments dated to this time period (Goodyear 2014). Immediately below the Morrow Mountain zone begins an extensive Early Archaic side-notched (10,000–9500 B.P.) occupation consisting of Taylor points and represents the first discernible occupation after Clovis (Figure A24–4 and 4–22). The Late Paleoindian period is poorly represented at Topper with only a single Redstone, Suwannee and Dalton point recovered from 854 square meters of excavated sediments. With the exception of the Suwannee point, these points were recovered from the Topper Hillside excavations.

To date, 174 formal diagnostic bifaces and biface fragments have been recovered from the Clovis contexts at Topper (Smallwood 2011). Of these, 20 have been recovered from the Terrace while 154 derive from the Hillside. A total of four finished Clovis projectile points have been found at the Topper Site, two of which have been recovered from colluvial deposits on the Pleistocene Terrace and were produced from Allendale Coastal Plain chert (Smallwood 2011). A sample of the Clovis bifaces recovered from Topper is presented in Figure A24–5 (Figure 4–23).
Figure 4–23
Clovis preforms and bifaces from the Topper Site. A; complete, B; biface base, C; biface base, D; complete, E; biface base, F; biface base.
Compared with the Woodland and Archaic cultures at Topper, the Clovis component is substantial in areas of the Pleistocene Terrace to the north of the primary 5m x 9m excavation block. The Clovis deposits at Topper represent one of the largest quarry-related sites in the southeastern U.S. Moreover, the Holocene and Late Pleistocene deposits appear to be stratigraphically intact with little evidence of artifact mixing. A spatial analysis of the distribution of diagnostic projectile point types from the Holocene Clovis deposits further confirm this proposition (Figure A23–17). Apart from the Clovis points, additional artifacts recovered from the Clovis – age deposits include unifaces, denticulates, blades, cores and utilized flakes. Figures A24–7 through A24–10 present a sample of blades and blade cores that have been recovered from Topper (Sain 2012).

Goodyear (2007) and King (2012) noted the presence of flakes and possible artifacts from stratigraphic units below the Clovis deposits at Topper. This assemblage occurs within and at the base of unit 2a and 2b, and extends into the Pleistocene terrace below. To date, evidence of pre Clovis at Topper has been restricted to the Alluvial terrace. Although a substantial amount of fieldwork has been undertaken on the hilltop portion of the site, there has been no evidence of chipped stone tools or other artifacts below the Clovis horizon other than a few small biface flakes attributed to downward drift or bioturbation. The absence of artifacts of potential pre Clovis age from this area of the site is intriguing given the abundance of such items on the alluvial terrace at the base of the hillside slope. A number of possible scenarios could explain this pattern. These results could imply that existing pre Clovis occupants were not intensively occupying the hilltop area of the site, or what has been interpreted as a pre Clovis occupation on the Terrace is in fact the byproduct of naturally chipped chert items that have accumulated at the base of the hillside slope. Likewise, evidence of pre Clovis could exist on the hilltop but has yet
to be identified. This study is designed to examine the Topper assemblage from the Terrace floodplain in greater detail, and provides a comprehensive lithic analysis of the materials below the Clovis deposits at the site. The following chapter provides a discussion on lithic analysis with special emphasis on the various approaches to chipped stone tool analysis and how to differentiate artifacts produced by humans from items that can form by way of natural processes.
CHAPTER V
IDENTIFYING ARTIFACTS FROM GEOFACTS: APPROACHES TO CHIPPED STONE TOOL ANALYSIS

Introduction

One of the most important objectives of archaeological investigation is the verification and reconstruction of past life-ways from an assemblage of material culture. Stone tools and chipped stone debris (the byproducts of their manufacture) are the most abundant material recovered from prehistoric archaeological sites. Given the abundant and diverse strategies implicit in stone tool production it is important for the archaeologist to have a comprehensive knowledge of lithic fracture mechanics, and the attributes consistently found to occur as the result of different strategies of manufacture. By studying these processes, archaeologists may form an understanding of past human behavior with regard to the manufacture of stone tools. Lithic items produced by natural processes can resemble chipped stone tools, and it is essential that the lithic analyst is able to distinguish stone tools deposited as part of the behavioral system from those that are produced in nature. This is critical at a site like Topper, where the pre Clovis assemblage has received widespread public attention yet only partial technical analysis, and indeed, is viewed with skepticism by many Paleoindian researchers (Wheat 2012). An understanding of context and how chipped stone artifacts interact with the natural environment is critical in this regard to infer past human activity. In this chapter a literature review focusing on lithic research and lithic attribute analysis is provided. Specific emphasis is given to flake formation, debitage analysis, approaches to stone tool analysis, and lithic taphonomy. The lithic analyses discussed herein are employed in the following chapters to evaluate whether natural or human agents were responsible for the patterns observed in the archaeological record and also to determine the processes leading to their deposition.
I conclude this chapter with a discussion on the role of site formation processes in the distribution of lithic material culture.

**Lithics, Terminology and Basics of Stone Tool Production**

Stone is one form of raw material that has been used by practically all human cultures, and the manufacture and usage of chipped stone tools covers 99% of all of human prehistory. Chipped stone materials represent the most plentiful artifact form found on prehistoric sites (Andrefsky 2005). Unlike material remains produced from organic materials, stone has the added advantage to withstand various environmental, geological, and human induced site formation processes such as erosion, deterioration, and decay (Andrefsky 2005:1). As such, in some contexts, chipped stone tools and debitage produced as waste from tool manufacture may be the only record of human behavior that archaeologists have at their disposal for reconstructing the past.

The examination of chipped stone tools and chipped stone debris is known as lithic analysis. The term lithic derives from the Greek work for stone, and is used in this study to refer to all culturally modified stone materials found on prehistoric sites (Andrefsky 2005:11). Chipped stone artifacts fall into two categories: objective pieces or detached pieces (Andrefsky 2005:12). According to Andrefsky, “objective pieces are stone items that have been hit, cracked, flaked, or modified in some way”, and are therefore distinguished from detached pieces, or those “removed from objective pieces during the modification process” (Andrefsky 2005:12).

Lithic analysts are interested in examining stone artifacts to obtain some information about prehistoric life-ways and behavior. One way this is accomplished is through analyzing the byproducts (detached pieces) of stone tool manufacture. Unlike other production technologies such as ceramic manufacture, stone tool production is a reductive process, the byproducts of
which can be examined to reconstruct particular behaviors inherent in the manufacture process. These byproducts are referred to as debitage, and fall under the detachment category of chipped stone materials. While there are multiple categories of debitage, Fish (1981:374) has defined debitage as all stone artifacts of cultural origin that are not cores or tools, a major subset of which are flakes. Flakes are important to archaeologists and lithic researchers alike as the attributes characteristic of a given flake detachment may provide valuable information regarding the strategy of reduction, the technique(s) used in manufacture, or for what purpose the piece was used. Figure 5–1 illustrates a typical flake showing common elements and terminology.

Throughout the history of lithic research, there have been many definitions for a flake (Cotterell and Kamminga 1987). Andrefsky (2005) defines a flake as any “portion of a rock removed from an objective piece by percussion or pressure”, the objective piece being the rock reduced by the removal of flakes (Andrefsky 2005:255). According to Cotterell and Kamminga, a flake is “any fragment detached from a nucleus, and not limited to the conchoidal variety” (Cotterell and Kamminga 1987:676). Shott defines a flake as any object detached from a larger stone mass; this treatment, however, includes natural as well as human-induced fracture (Shott 1994:70).

One reason for the seeming abundance of definitions for a flake stems from the notion that flakes can vary significantly in morphology and condition based on the technique(s) used to detach them. Flakes removed in a controlled manner typically exhibit technological and morphological characteristics that provide clues to the manner by which they were detached (Andrefsky 2005). Technique refers to the design implement or implements chosen for lithic reduction. Examples of lithic techniques include hard hammer percussion, soft hammer percussion, or pressure flaking. Known as the Application load typology, Cotterell and
Figure 5–1.

Kamminga (1987) have identified a number of ways that flakes may form, and they suggest that different techniques employed in flake detachment may result in a wide variety of technological and morphological attributes that the detached pieces may exhibit. Table 5–1 presents different lithic reductive techniques and the attributes commonly found on the detachments produced from each. Hard hammer percussion such as with a quartzite hammerstone is often considered the technique of choice for early stages of manufacture and produces detachments that are thick and have prominent points of applied force. A soft hammer such as a billet made of wood, bone or antler typically produces detachments that are flat and thin and have small diffuse points of applied force. Soft hammer methods are thought to occur during secondary stages of lithic manufacture such as thinning a biface.

A third reductive technique, pressure flaking, uses direct force by pressing as opposed to striking the objective piece, and results in flake detachments that are typically smaller, thinner, and lighter than percussion flakes. However, Andrefsky cautions that small, thin and light flakes may occur as the result of any reductive technique and therefore it is difficult to distinguish reductive technique based solely on the attribute of size (Andrefsky 2005). Hard hammer percussion, soft hammer percussion and pressure flaking techniques have in common the characteristic that they all employ a specific fracture condition known as hertzian, conchoidal fracture as means to detach a flake. Alternative reductive techniques such as bipolar reduction may be different and can result in fracture patterns that are unique. Therefore a discussion of fracture mechanics is essential and necessary to any discussion of flake formation.

In the section that follows, the mechanics of flake formation and the individual attributes of a flake are discussed in greater detail and provide a description of the common elements and terminology used to depict them. Because there are many definitions for a flake, and a seemingly

endless array of methods for examining them, problems can sometimes arise when lithic analysts attempt comparisons of debitage assemblages that have been defined based on differing recording criteria. Therefore it is important to use a standardized set of methods and terminology to recognize and record attributes on flake debitage if we are to gain some insight into the ways in which people made and used stone tools in the past (Andrefsky 2005). It is of significant importance to establish definitions for the attributes of flakes and chipped stone artifacts to ensure replicability for future research endeavors. Appendix 45 gives a glossary of terms discussed in the text with regard to lithic analysis. a discussion on debitage analysis concludes this section.

**Flake Formation and Fracture Mechanics**

As defined above, a flake is any lithic material detached from a given mass of stone. Flake formation is dependent on the theory of hertzian fracture. The name derives from Heinrich Hertz, a German physicist who was the first to conduct scientific experiments on the principle of the cone fracture. Hertz observed that when a solid, firm, and rounded precursor strikes “perpendicularly” into the surface of an “isotropic brittle solid”, a hertzian cone fracture is produced (Cotterell and Kamminga 1987:685; Hertz 1896; Lawn and Marshall 1979). The concept has been likened to the shatter pattern produced when a bb pellet strikes a pane of glass. The same concept applies to the fracture of any brittle solid, including stone. When sufficient force is applied to the surface of stone, the resulting energy travels through the material and produces what is known as the hertzian cone. The hertzian cone subsequently expands downward into the nucleus at an angle relevant to the angle of applied force. Once a hertzian cone is formed, fracture will continue through the nucleus only if the force of the blow was “sufficient to accelerate and overcome the inertia of the material that is to be removed” (Cotterell and
Kamminga 1987:685). The result of applied force exits the nucleus, and depending on the angle, affects the condition of the flake termination. If the nucleus was struck close to the margin, then only a partial hertzian cone will be visible on the resulting interior surface of the flake.

Cotterell and Kamminga (1979, 1986, 1987) provided the foundation of our current understanding of fracture mechanics as it pertains to the process of flake formation. They have found that the formation of flakes occurs in three distinct phases. These phases include initiation (hertzian, bending, wedging), propagation (stiffness controlled, compression controlled, and termination (Cotterell and Kamminga 1987). Initiation refers to the means of initial contact between a precursor or striking implement and the objective nucleus from which a flake is to be detached.

Hertzian initiations form when increased loads between the indentor and brittle solid ultimately lead to the formation of cracks in the surface of the solid (Figure 5–2 and 5–3). According to Cotterell and Kamminga, the “cracks grow downward as load application is increased” until reaching a threshold of “three times the contact area radius”, at which point additional growth falls under the influence of alternative mechanisms (Cotterell and Kamminga 1986:685). Wedging initiation occurs when an indentor strikes the objective piece “well away” from its margin, or if the edge angle is greater than 90 degrees (Cotterell and Kamminga 1987:688). According to Cotterell and Kamminga, such initiations are more common when the nucleus being struck is flawed (Cotterell and Kamminga 1987). Wedging initiation often results in the formation of multiple cracks and fractures from the area “surrounding the primary crack” and can also occur from the bottom of the objective piece (Cotterell and Kamminga 1987:689).

In bending initiation, fracture occurs when applied pressure of the indentor produces a crack near, but not at the initiation face and develops downward at a 90 degree angle. A bend

break occurs when the flake is struck at the midpoint without being supported on each end. In addition to intentional lithic manufacture, this form of fracture can occur if natural pressures such as sediment load exert force on a given lithic body that is not supported on each end, and that is in a matrix with many numerous and larger lithic bodies. Bending initiations can also form as the result of trampling, either from humans or animals.

The Propagation phase refers to the means by which cracks appear in a solid form and grow under different types of stresses (Figure 5–4). Propagation is influenced by different offsetting stresses (tensile, bending and compressive) resulting from the degree and direction of applied force, and can affect the path a crack takes through the core (Cotterell and Kamminga 1987). Termination refers to the “mechanics involved in the final detachment of a flake from a nucleus”, and are the result of changes in the angle and amount of applied force, as well as the morphology of the nucleus (Cotterell and Kamminga 1987:698) (Figure 5–5). Using the above criteria, Cotterell and Kamminga recognized three distinct flake types based on fracture mechanics. These flake types include the conchoidal flake, the bending flake, and the compression flake.

**Individual Flake Attribute Analysis: Flake Types**

*Conchoidal Flakes*

Conchoidal flakes are formed through hertzian initiation, and result in “stiffness-controlled propagations” (Jennings 2011:1). Such flakes may terminate as feather, hinge, or step terminations. They are characterized as having a bulb of force, and are often produced with the aid of a hard hammer percussor such as a hammerstone (Andrefsky 2005; Cotterell and Kamminga 1987). Conchoidal flakes are most commonly a byproduct of biface manufacture.
Illustration showing the types of propagation in the mechanics of flake fracture as described by Cotterell and Kamminga 1987 (Image adapted from Cotterell and Kamminga 1987:684).

**Compression Flakes**

Unlike conchoidal flakes, compression flakes are a product of wedge initiation, whereby the application of force is focused away from the margin of the objective piece, and upon what is considered the center of the hertzian cone (Andrefsky 2005). Compression flakes typically result in axial termination (Odell 2003). Figure 5–6 illustrates attributes of a compression flake. Compression flakes are often formed through a technique known as bipolar reduction, whereby the flake is detached by placing the objective piece between an anvil and the point at which the percussor initiates contact. Useable flakes are considered to be the primary goal of bipolar lithic production (Diez-Martín et al. 2010). Because compression flakes are struck with support from below (anvil stone providing opposing force opposite the point of impact), they will occasionally exhibit two impact marks: one resulting from the applied force from above, and the second resulting from compressive stresses acting between the objective piece and anvil.

Diez-Martín et al. (2011) identified three methods of bipolar reduction: vertical axial, horizontal axial, and non–axial or oblique (Figure 5–7). Each method results from the way applied force strikes the objective piece. In vertical flaking, the objective piece is struck with applied force emanating downward from above and “perpendicular to the core and anvil” (Diez-Martín et al. 2011:692). In horizontal flaking, the objective piece is struck from above; however, the “axial length and the striking plane do not coincide” (Diez-Martín et al. 2011:692). In non-axial flaking, the objective piece is struck in such a way that applied force is directed away from the point of contact with the anvil (Callahan 1987:13). According to Diez-Martin et al. (2011:692), “Without a distal contact point, flakes obtained by means of an oblique method do not differ substantially” from conchoidal flakes. However, because horizontal and vertical flaking techniques produce detachments from different regions from a given objective piece than
Figure 5–6

non-axial flaking, compression flakes produced by such methods typically have attributes that are technologically distinct from conchoidal flakes.

**Bending Flakes**

A final type of flake is the bending flake (Figure 5–8). Bending flakes are initiated when raw material cleaves at a point away from the load application of force (Andrefsky 2005). Like conchoidal flakes, bending flakes also form through stiffness-controlled propagation, and may also terminate as feather, hinge or step terminations. A special form of bending flake is the bend fracture flake, noted for their step terminations (Jennings 2011). In lithic production, bend fracture flakes are produced when the point of impact is concentrated at the mid-point of an existing biface or flake (Cotterell and Kamminga 1987; Jennings 2011), and have been identified from a number of Paleoindian assemblages (Bergman et al. 1987; Ferring; 2001; Frison and Bradley 1980; Waters et al. 2011). If there is no force directly opposite the point of impact, then bending fracture will lead to the flake snapping transversely. By contrast, if an opposing force is placed directly beneath the point of impact, "compression fracture will propagate from the striking surface and result in a radial break", whereby the flake snaps into three or more pieces (Cotterell and Kamminga, 1987, Jennings 2011). In some cases, such breaks can create fracture angles close to but not quite ninety degrees.

An experimental study by Bergman (1987) found a number of diagnostic attributes that are consistently identifiable with bend fracture flakes. These include: points and cones of percussion, incipient cones, dorsal crushing at the point of impact, wedge shaped fracture lines, and lips or protrusions along the terminal end of a break face on a bend break resulting from bending initiation. The occurrence of lips along the break margin of a bend break flake forms as a byproduct of applied bending force to the object, and therefore does not likely occur as
Figure 5–8
Example of a bending flake with associated attributes. Note the different break angle and only a single direction of impact stress compared with the compression flake (Image adapted from Jennings 2011:3).
resulting from natural weathering processes. Other attributes characteristic of bend fracture flakes include an interior surface, compression lines, lips along the break margin, and no bulb of force.

In a more recent study, Jennings (2011) examined the attributes of flakes experimentally produced by bend fracture initiation, and those incidentally produced in biface reduction. Accordingly, bend fracture flakes were found to be significantly thicker, and exhibit a higher occurrence of lips than hertzian flakes. Hertzian breaks were found to have more acute break angles than bend fracture flakes. Jennings (2011:3) experiments also demonstrate that lips occur significantly more frequently on bending fractures that have been intentionally struck than on hertzian, radial or unintentional fractures. Finally, significantly more flakes produced by bend fracture techniques have impact fractures than flakes fractured during biface reduction (Jennings 2011). Jennings concludes that intentional flake fracture “typically leaves evidence of the point of impact on fractured fragments” (Jennings 2011:7).

**Individual Flake Attribute Analysis: Flake Attributes**

Lithic analysis can be used as a tool to distinguish and categorize flakes through individual attribute analysis. Attributes are individual features of artifacts that can be observed or measured, and are used to distinguish one artifact from another. Attributes are important for identifying variability among lithic assemblages. According to Andrefsky (2005), many debitage studies emphasize why particular flake attributes are important for understanding certain aspects of technological behavior but “never show how to record such attributes in a consistent and reliable manner” or provide the reasoning behind the selection of some attributes over others (Flenniken 1978; Magne 1985).
The first aspect of any technological analysis of chipped stone materials is for the analyst to determine what he or she wants to learn from the data that have been acquired. The flake attributes selected for analysis should be chosen based on a set of criteria that can reliably inform about a research question. Certain flake attributes have been shown to be more informative about some aspects of stone tool manufacture than others. Therefore it is important to select for analysis those combinations of attributes that best reveal aspects of the lithic technology that are in question.

All attributes of lithic flakes and chipped stone debris are classified as either morphological or technological attributes. Morphological attributes provide information on the characteristics of artifact shape (length width, thickness) and weight. Morphological attributes can be recorded on complete or broken flakes, as well as on individual characteristics of a flake (Figure 5–9). Technological attributes inform about particulars of the manufacture process and include attributes of the exterior and interior surfaces, flake condition and flake class (Figures 5–1, 5–10 to 5–14). Condition refers to completeness (whole, proximal, distal), and presence or absence of post-detachment modification. Class refers to position in the reduction sequence to which a particular specimen belongs, and is identified through examining the presence and absence of cortex on the exterior surface. Below I discuss technological attributes commonly recorded on flakes. These attributes include characteristics of the exterior and interior surfaces, flake condition and flake class. These attributes can inform a great deal about raw material condition, how a given flake was removed from a nucleus, and technological decisions made during the manufacture trajectory.

*Flake Attributes of the Interior surface*

**Striking Platform**

The striking platform or point of applied force is the point on a core or objective piece at which a “single flat surface” is struck or hit to remove a detachment. The point on a detached flake that contains the remnant of the objective platform surface is known as the platform remnant, and is referred to as the proximal end of the flake (Andrefsky 2005). The striking platform is an important lithic attribute since specific characteristics of the platform surface such as size, shape, and condition can convey information about the original objective piece, manufacture technique, and reduction trajectory. Striking platforms can have flat or plain surfaces, they can exhibit faceting (single or multiple), or they can display evidence of grinding (Figure 5–12). Striking platforms that are shattered often reflect hard hammer percussion whereas wide, flat points of applied force are often the result of soft hammer percussion. Modified striking platforms are those that are faceted or that exhibit grinding. Faceting and grinding are the result of actions taken to ensure added control of the direction and detachment of a flake as it is removed from a core. Plain striking platforms lack evidence of modification and are typically featureless. Such platforms can occur as a result of natural collisions of lithic material or by human agency.

**Bulb of Force**

Immediately below the striking platform on the proximal, interior surface of a conchoidal flake is the bulb of force (Figure 5–1, 5–13). The bulb of force results from the influence of compressive forces as the hertzian cone “turns toward the outside of the objective piece” (Andrefsky 2005:253). This feature may be identified as a raised hump on the interior surface of the flake. The bulb of force may be prominent (salient) or flat (diffuse) and may indicate the type
of percussor used in flake production or the angle of applied force (Andrefsky 2005:20). While a bulb of force is typically found on most flake types (discussed below), some flake types such as bending flakes lack a bulb of force as the initiation occurs away from the point of applied force.

**Eraillure Scar**

An eraillure scar is the negative of a removal flake that separates from the mid-point of the bulb of force as a flake is detached from a nucleus (Figure 5–1, 5–13). An eraillure flake is a product of differential force waves that travel through the objective piece once applied force is initiated. According to Andrefsky, an eraillure flake is formed when “an inferior wave contacts a dominant wave as the bulb of force is being created” (Andrefsky 2005:22).

**Compression Rings/Ripple Marks**

Compression rings are undulations on the interior surface of a flake and radiate in the direction away from the bulb and point of applied force. When a striking platform is missing, compression rings are attributes that are helpful in determining the direction the flake was struck.

**Flake Attributes of the Exterior Surface**

**Removal scars**

Removal scars are the negatives of prior flake detachments that occur on the exterior surface of a flake (Figure 5–13). Lithic analysts have used the number and pattern of removal scars on the exterior surface of a flake to determine the point in the reduction trajectory that the flake was detached. Later stages of reduction are thought to have higher numbers of removal scars than flakes detached during early stages of reduction. Moreover, the directionality of removal scars is thought to inform about reduction strategy (blade versus biface manufacture).
**Arrises**

Arrises are ridges on the exterior surface of a flake that result from the intersection of two or more flake removals. Also referred to as the dorsal ridge, the arris is used to delineate the margins between flake removal scars on the exterior surface of the flake.

**Flake Condition**

The term flake condition refers to a measure of completeness (whole, proximal, medial distal), and is used to differentiate complete flakes from those that are broken or are flake fragments. Condition can also refer to the presence or absence of post-detachment modification on a flake surface, thermal alteration, or patination/staining.

For analytic purposes, a flake can be divided into four potential sections. These include complete flakes, proximal flakes, medial flake segments, and distal flake terminations. Three of these categories are presented in Figure 5–10. The proximal end of a flake is that end that received applied force and contains evidence of a striking platform or bulb of force. The flake distal segment is the terminus of a flake. A flake medial segment refers to the mid-point of the flake. The terms proximal, distal and medial are typically used to identify and describe broken flakes and flake fragments and are important attributes in assessing debitage categories.

In addition to measures of completeness, the presence or absence of post detachment modification is often used in flake attribute analysis. Modification includes utilization or retouch, and applies to any type of trimming (unifacial or bifacial), at any angle, that is restricted to any margin or edge of an artifact or flake (White et al. 1963). This may be accomplished through either production, use, or rejuvenation of a tool during its life span.

In addition to post-detachment modification, flakes are subject to natural processes that can affect the appearance of the exterior surface of the flake. One such process is referred to as
patination. Patina refers to an accretional process whereby mineral deposits on an artifact or flake surface gradually increases by steady addition over time. One form of patina is river staining, and is a darkening of the flake surface because of being submerged or worn by fluvial processes for an extended period. River patination is an important attribute as it can inform about the geological processes affecting an artifact over time. Moreover comparisons of the presence or absence of river patina on flakes on an archaeological assemblage can also be used to assess issues relevant to raw material procurement.

The distal end of a flake is often characterized by its termination type, which represents the manner in which the distal end of a flake detached from a nucleus. Termination types include feather, hinge, step, or plunging (overshot or outrepassé) and are illustrated in Figure 5–5. Hinge, step, and plunging terminations are often considered to be errors, whereas feather terminations are the natural progression of a flake detachment as it propagates away from the nucleus. Feather terminations form as the flake gradually decreases in thickness as it is detaching from the core, and are considered a continuation of propagation (Cotterell and Kamminga 1987). Hinge terminations are terminations at the distal end of a flake that are rounded or blunt (Andrefsky 2005). Such terminations form when the applied force, during propagation, rolls away from the parent body (nucleus). Step terminations occur when there is an “abrupt change in the direction of a crack” during flake detachment (Cotterell and Kamminga 1987:700). Such terminations are thought to be the result of “insufficient energy available to complete a fracture or because the crack intersects a significant flaw “in the objective piece (Cottrell and Kamminga 1987:700). When such a flake breaks prematurely during detachment, it may leave a distal terminus that forms a 90 degree angle relative to the point of applied force. Plunging flakes are the opposite of hinged flakes and are the result of applied force rolling back towards the nucleus.
Flake Class

Class refers to a position in the reduction sequence to which a particular flake belongs, and is identified through examining the presence, amount and absence of cortex on the flake exterior. Flake classes include cortical, secondary, and interior (Figure 5–14). Cortical flakes lack evidence of removal scars on the exterior of surface of the flake. Secondary flakes have removal scars, yet still exhibit some cortex. Interior flakes do not exhibit any evidence of cortex on the flake exterior and are considered to represent later stages of the reduction continuum. Studies that document the presence and quantity of cortex on the exterior surfaces of artifacts are geared toward identifying patterns in the reduction stage or sequence.

Debitage Analysis

While individual artifact attribute analysis can be an integral approach to understanding human lithic reduction behavior, it may not always be possible to examine the attributes of all flakes from an assemblage. Moreover, some researchers have suggested that an analysis focused solely on attribute definitions is too subjective (Sullivan and Rozen 1985). Therefore, it may be useful to combine individual artifact attribute analysis with approaches that examine the assemblage as a whole (debitage analysis), to make more informed interpretations of chipped stone assemblages.

Debitage analysis is the examination of an entire assemblage of flaked stone debris in an effort to understand the relationships between debitage attributes and stone tool manufacture behavior (Andrefsky 2005). A primary goal of debitage analysis is to provide the analyst or researcher the ability to make accurate assumptions about the purpose of lithic manufacture. According to Andrefsky, while there is a wide range of approaches for analyzing debitage, debitage analysis may be conducted from the “perspective of an individual artifact”, or from the perspective of a population of artifacts (Andrefsky 2005:113). However, because individual
attribute analysis can be a “time consuming” process, one method to overcome this problem is to group different categories of debitage into types based on one or more shared characteristics (Andrefsky 2005). Such “types” are considered to contain important information regarding human behavior. Andrefsky refers to this approach as a typological approach to debitage analysis. One popular typological approach to debitage analysis is the Free Standing Typology. Free Standing Typologies typically focus on a set of criteria that is replicable, yet do not make use of any information regarding the “final interpretation of the debitage” in question (Andrefsky 2005:127). One example of the Free Standing Typology is the Interpretation Free Model (IFM) developed by Sullivan and Rozen (1985) (Figure 5–15).

*Interpretation Free Model*

In a seminal study on flake analysis, Sullivan and Rozen developed an “Interpretation Free Model” (IFM) for flake analysis (Sullivan and Rozen 1985). Their method incorporates three dimensions of flake variability, each with two possible outcomes (Sullivan and Rozen 1985). The flake variables include a single interior surface, a point of applied force, and intact margins. The outcomes for each variable are given as “presence” or “absence”. The dimensions of variability were selected, because they do not contain inherent categories that may be tied to specific interpretations. Rather, such variables are objective, and thus may “enhance replicability” (Sullivan and Rozen 1985:758). Sullivan and Rozen define complete flakes as those artifacts having a single interior surface, a complete or partial striking platform, and intact margins with a clear point of termination (King 2012:73; Sullivan and Rozen 1985). As a focus solely on complete flakes may partially overlook some of the variability inherent within a given
assemblage, the IFM allows for the classification of broken flakes and debitage (Carr and Bradbury 2001). Accordingly, flake fragments and broken flakes are those pieces that have a discernible interior surface, yet lack a point of applied force or intact margins respectively. Sullivan and Rozen’s IFM is an important contribution to debitage analysis as it stresses the significance of interpretation free categories in flake identification, and may be used to differentiate complete flakes from debris. The IFM is critical to this study because lithic debris can form because of cultural or non-cultural (natural) processes. Natural processes such as weathering and erosion can create or modify a lithic assemblage and therefore it is essential to discuss how “differential fragmentation, attrition, and the alteration of lithic materials might affect archaeological patterning” (Rasic 2004:114). In the section that follows, I consider the role of lithic technology in the formation and distribution of lithic materials.

**Lithic Technology and Chipped Stone Tool Typology**

Lithic technology may be defined as the extensive array of methods employed to manufacture usable tools from a variety of lithic raw material types. Andrefsky (2005) has presented a morphological typology for the classification of all chipped stone artifacts (Figure 5–16). At the highest level, chipped stone artifacts are categorized as either tools or non-tools (debitage). Non-tools include such items as flakes and non-flake angular shatter (Andrefsky 2005). Tools may further be subdivided into biface tools and non-biface tools. According to Andrefsky, the non-biface tool category includes two distinct tool types: core tools and flake tools. Flake tools consist of all modified lithic implements that have been produced on flakes, and include such artifacts as unifaces, scrapers, blades and utilized flakes. All tools that are not flake tools or bifaces are classified as core tools. These exhibit flake removals on the exterior surfaces and “must contain some form of retouch or modification” (Andrefsky 2005:81).
Figure 5–16
Morphological typology for the classification of all chipped stone artifacts as defined by Andrefsky (2005:76).
The morphological typology for chipped stone tools allow for the analysis of lithic assemblages. Many lithic analysts classify chipped stone assemblages based on specific production technologies. These are often defined based on desired end product. Four lithic production technologies are considered here and include biface tool production, core tool production, flake tool production and bipolar reduction. The first three are components of Andrefsky’s morphological typology and are based primarily on flake removal strategies that utilize hertzian initiation. The fourth production mode, bipolar reduction, employs compressive or wedge initiations to aid lithic detachment. Compression flakes produced by bipolar reduction are commonly flat as opposed to curved.

Bifaces are objective pieces that have two sides that converge to create a single margin that “circumscribes the entire artifact” (Andrefsky 2005:178). Biface production involves the removal of flakes from each of two sides of the objective piece. Bifaces can serve as raw material sources to be further reduced into stone tools, as projectile point performs, as chopping or slicing tools, or hafted to be used as projectile points. Extensive research has been undertaken to understand the strategies employed in biface production by prehistoric peoples. These studies typically involve analyses geared toward understanding reduction stages or sequences. (Callahan 1979; Frison and Bradley 1980), trajectories, or tool function (Frison 1968).

Core tool production involves the removal of flakes from an objective piece in either a unidirectional or multidirectional form (Andrefsky 2005). The flake removals detached from a core may be used as tools, the core itself may be modified and fashioned into a tool, or the core may serve as a source of raw material for additional flake removals (Figure 5–17). Flake tools are artifacts that have been detached from a core and subsequently undergone some form of modification. Flake tool production involves the detachment of flakes from an objective piece
Figure 5–17.
Lithic manufacture trajectory employed in flake core manufacture, (Sain 2011).
followed by intentionally retouching the flake margins for use or using them unaltered, thus providing some evidence of use-wear along the edge. A number of artifact types are made on flakes. Flakes produced from unidirectional cores typically take the form of blades (Ackerman 1992; Andrefsky 1987; Hiscock 2002) and are detached using hertzian initiation. Other common forms of flake tools include end and side scrapers, unifaces, denticulates and utilized flakes.

A fourth lithic reduction technology, bipolar reduction, refers to a form of core technology that employs the use of compressive forces to detach a flake from a core. Bipolar technology involves placing an objective piece on an anvil and “striking it with a hammer to split or remove a flake detachment” (Andrefsky 2005:253). This action results in a series of characteristic attributes that may be observed on either the core, the detached flakes, or both. As discussed above, the flakes detached in bipolar reduction often exhibit evidence of impact on both the proximal and distal end of the flake and have compression rings that “move in two directions toward one another: (Andrefsky 2005:253). Bipolar reduction results in compression flakes produced by wedging initiation, or bend fracture flakes if there exists no opposing force opposite the point of impact. However, bipolar production also produces debitage residue that often takes the form of blocky shatter, and is therefore difficult to distinguish cultural debris from the material byproducts of natural fracturing events.

Goodyear (1993) suggested that bipolar production by anvil reduction was one way to extend the use-life of stone tools. In areas of raw material uncertainty, bipolar reduction could be used as a method to obtain a sharp flake from a core. By contrast, Shott (1997) found that bipolar reduction was an expedient method to obtain flakes when raw material was readily available and not in short supply. Accordingly, more artifacts reflecting bipolar anvil reduction were found at
sites where raw materials were locally abundant. Because of the abundance of materials, flakes could be quickly and easily detached from bipolar cores without concern for error.

**Lithic Taphonomy**

There are a variety of natural processes that can alter or disturb an assemblage of culturally chipped stone artifacts. Mechanical weathering, hydric forcing, sediment consolidation, cryoturbation, thermal stress, trampling, colluvial action, and fluvial action are all processes that can alter an existing archaeological assemblage subsequent to its deposition. However, it is also possible for these natural processes to generate a suite of stone debris from non-cultural or unmodified cobbles. For example, geological processes can affect stone cobbles in such a way that can lead to the formation of lithic products that mimic the attributes of culturally chipped stone artifacts. Therefore, it is now generally accepted that the ways by which natural processes can affect lithic materials should be understood prior to making any “behavioral interpretations from a lithic assemblage” (Eren et al. 2011:202).

The effect that natural processes have on stone materials has been referred to as lithic taphonomy (Eren et al. 2011). The concept of taphonomy was initially defined as “the study of geological processes of the transition of animal remains from the biosphere into the lithosphere” (Efremov 1940:88). In archaeology, taphonomic studies are typically employed to investigate faunal remains and to account for the processes that affect an animal’s death, burial and subsequent recovery. However, Eren (2011) suggested that chipped stone artifacts can also interact with the natural environment and that such interrelationships can play a significant role in altering that artifact’s final cultural context and even appearance. Importantly, these changes can affect lithic attributes that are frequently measured in debitage analysis. Therefore, it is important not only to identify the various taphonomic processes that might be active on an
archaeological site, but to also determine what debitage attributes are characteristic byproducts of each process. Most essential is to distinguish taphonomic process from the lithic byproducts of cultural process, and specifically to assess whether a given chipped stone taphonomic process has modified stone tools in such manner that they could be misinterpreted as cultural (Eren et al. 2011). Below I briefly summarize some of the most important taphonomic processes that have the potential to alter or disturb lithic materials, and their consequences with regard to context and the archaeological record.

*Mechanical Weathering*

Principles from mechanical weathering can be used to help identify the causal mechanisms responsible for producing artifact patterning in archaeological deposits. The processes by which rocks weather can greatly affect the mechanical stability and internal structure of lithic materials over time. Mechanical weathering is defined as the “erosion or breakdown of rock into smaller fragments by natural and physical agents” but without significant change in chemical or mineralogical makeup (Boggs 1987:4). Mechanical weathering encompasses all external processes that transform solid rock into sediment without changing the rock’s mineral composition. According to Robinson and Williams (1994), three primary factors control rock weathering. These factors include the mineralogical make-up of the rock itself, climate conditions, and the length of time in which weathering processes have operated.

The mineralogical make up of a lithic body influences the degree to which it weathers. Lithic bodies that have mineral constituents consisting of small particle sizes tend to weather quickly that those with larger particle sizes. It follows then that artifacts produced from lithic raw materials consisting of small particle sizes may exhibit greater degrees of weathering than those
that have large particle sizes. Because differential weathering is dependent on raw material type, such processes can greatly affect the visibility of the archaeological record.

Climatic factors are crucial to the rate of rock weathering. In sedimentological contexts, the most common climate conditions that influence natural unmodified lithic weathering include episodes of heating and cooling (temperature), and immersion of the lithic body in groundwater and subsequent drying (hydric forces). For example, as a stone is heated it slowly expands. This process leads to specific tensile, compressive, and sheer stresses along granular boundaries within the lithic substrate (Weiss and Marsan 2004). Subsequent cooling results in lithic contraction, and the “progressive loss of cohesion along grain boundaries” (Weiss et al. 2004:402). Over time, lithic items that are subjected to prolonged cycles of heating and cooling may eventually fracture.

_Frost Wedging_

One of the most common temperature-dependent types of mechanical weathering is known as frost action or frost shattering, frost wedging or cryofracturing. Frost action refers to the mechanical weathering of stone induced by stresses created by the freezing of water into ice. When water freezes within the pores, cracks and joints of rock, it expands, leading to the formation of stresses within the rock, eventually causing it to split, break up, or disintegrate. Frost weathering is primarily determined by the frequency and intensity of freeze thaw cycles and the material constituents of the rocks subjected to weathering. Therefore, it is traditionally considered a process that affects lithic materials in northern or Arctic latitudes but can occur in any region where freeze thaw cycles occur with frequency. These cold climate processes can all
produce natural features on the stone surfaces that lithic analysts should not confuse with cultural features.

**Cryoturbation**

Research has shown that repeated cycles of freezing and thawing not only affect the mechanical stability of lithic bodies themselves but can also disturb the soils in which such bodies are situated (Bockheim et al. 1998). Cryoturbation or frost churning refers to the mixing of sediments from multiple soil horizons as a result of freezing and thawing and should not be confused with frost wedging which affects the mechanical stability of the rock itself. Cryoturbation can redeposit archaeological materials into older or younger sediments thus obscuring the archaeological record. Excavation and intensive analysis are often required to determine whether archaeological deposits are in primary or secondary context. Evidence for cryoturbation is often seen in soils that have “irregular or broken, materials that have been incorporated from other horizons and show evidence of vertical and horizontal sorting” (Bockheim et al. 1998).

Cryoturbation and frost wedging are important mechanical weathering processes that can significantly alter or redeposit archaeological materials. As such, these processes have received considerable attention in the archaeological literature. Hilton (2003) provides a series of questions that archaeologists should address when conducting analysis of the spatial patterns of archaeological deposits. What duration have artifacts been exposed on the ground surface subsequent to leaving the “systemic context”? Have such materials been subjected to cyclical processes of burial and subsequent exposure? Under what circumstances are freeze-thaw (Figure 5–18) cycles capable of postdepositional transformation of the archaeological record, and can postdepositional processes disperse artifact assortments thus “masking: areas of potential
The effect of freeze-thaw processes on stone. A: water seeps into the cracks in rock. B: when water freezes it expands and forces materials within the lithic body to expand, ultimately resulting in C: the fragmentation of a portion of the original lithic body into two or more pieces.
anthropogenic activity? Freeze-thaw and cryoturbation processes can be evaluated through experimental programs designed to quantify the degree that these processes can rework materials or affect lithic bodies under controlled conditions. Hilton found that the nearer to the ground surface an artifact is situated, the more quickly it will travel upwards as a product of the freezing process (Hilton 2003). Moreover, rapid rates of burial provide fewer opportunities for cryogenic cycles to displace cultural materials (Hilton 2003:196). Therefore, it is important to consider deposition rates when gauging the effects of cryoturbation on archaeological deposits.

In a similar study, Rasic examined the effects of freeze-thaw processes on lithic materials through experimental procedures (Rasic 2004). Rasic found that the breakage and degradation of lithic artifacts attributed to freeze-thaw processes typically only occur on items that have previously undergone episodes of thermal stress. The cracks and cleaves along bedding planes formed by thermal fatigue ultimately leave rocks more susceptible to the effects of freeze-thaw cycles whereby water can penetrate, freeze, and further fragment a lithic sample (Rasic 2004:122). Thus, the influence of freeze-thaw processes would appear to be secondary to thermal stress.

*Hydric Forces*

Hydric forces influence the structural integrity of stone through the addition or reduction of moisture. Rocks that heat rapidly due to peak insolation and subsequently lose their moisture content are subject to greater mechanical stresses than those that remain cooler and wetter for longer periods when exposed to air (Coombes and Naylor 2012). These hydric parameters are affected by the grain size, weight, porosity, as well as the micro-structure of a given lithic body. The introduction of moisture into the pores of a given lithic body followed by periods of dehumidification lead to episodes of hydric shrinking and swelling, and ultimately “moisture
induced degradation” (Weiss et al. 2004:403). Drying of lithic materials is thought to lead to “negative pore pressures and consequent tensile stresses that pull the rock apart (Boggs 1987). In contrast, the absorption of water by lithic materials during phases of greater moisture creates swelling pressures that tend to push rocks apart” (Boggs 1987). Elliott (2008) has found that lower levels of moisture intake are more effective in producing weight loss among specific rock types. One may expect that rocks exposed to dry, arid conditions, should exhibit greater weight loss than those in moist environments. Rocks subjected to cyclic periods of wetting and drying will exhibit greater evidence of weathering and deterioration than those exposed to more temperate conditions.

Over time, hydric and temperature-induced “degradation” forces may lead to the formation of fissures, cracks, and cleavage planes within a given lithic body. Ultimately, fracture may ensue, and individual pieces may detach from the parent material. In such cases, the potential exists that the detached pieces may exhibit attributes common to some flaked stone technologies. As such, by examining how different temperature and moisture regimes affect the stability of rocks, it is possible to form a much broader understanding of the relationships between mechanical weathering processes and flaked stone taphonomy.

A byproduct of alternating wetting and drying cycles occurs as sediments in clays shrink and swell and cause a form of mixing referred to as argilliturbation. During dry periods, clay-rich sediments will shrink and crack. If occurring on archaeological sites, artifacts resting on the surfaces of these sediment formations may fall into the cracks, thus obscuring the visibility of the archaeological record. Through this process, argilliturbation can cause downward movement of archaeological constituents through soil cracks and subsequent upward movement of lithic materials during swelling episodes.
**Sediment Consolidation**

Lithic materials in buried contexts are subject to rearrangement or alteration as the result of changes in the volume of sediment load. Sediment consolidation or compaction is defined as the process(es) by which sediment volume is reduced in response to increased sediment density with “natural overburden loading” (Andrews 2006:460). Sediment consolidation typically occurs when the amount of void space in the sediment matrix diminishes as overburden increases (Figure 5–19). This action results in a more compact association of solid particles within the sediment (Andrews 2006). If exposed to such conditions for prolonged periods, solid particles within consolidated sediments can undergo significant rearrangement or even fracture. Because sediment consolidation can affect the spatial distribution, vertical displacement, orientation, or inclination of chipped stone artifacts, it is important to determine the means and degree to which sediment consolidation has affected an archaeological assemblage” (Andrews 2006).

A number of studies have simulated sediment consolidation on lithic materials in an effort to document and quantify the effect of this process on buried archaeological deposits (Andrews 2006; Eren et al. 2011). Most research identifies at least two ways by which sediment consolidation can disturb lithic assemblages following deposition. These include artifact displacement and artifact fracture. Artifact displacement refers to the displacement and movement of flakes within an archaeological assemblage. For example, artifacts can move through a sediment profile as sediment consolidation has significant influence on artifact inclination. Artifacts with horizontal or little inclination are typically assumed by archaeologists to reflect undisturbed contexts on an archaeological site. However, Andrews suggests that consolidation can transform assemblages with seemingly “random inclinations” into those with
Figure 5–19
Model of sediment consolidation. As the weight of sediment overburden increases, there is a corresponding reduction in void space resulting in a more compact association of solid particles within a sediment (adapted from Andrews 2006:463 and Eren et al. 2011:204).
apparently more deliberate patterning leading to the potential for misinterpreting the “depositional history” of a site (Andrews 2006:464).

Andrews finds the following regarding sediment consolidation: results of controlled simulations indicate that artifacts initially deposited with elevated inclination angles will experience greater reduction in inclination than artifacts originally deposited “at lower inclination” (Andrews 2006:468). Moreover as compressive forces increase on a body of sediment, so too does the extent to which artifacts will flatten within the sediment matrix. As consolidation increases, so too does the amount of downward movement of artifacts through a sediment profile. Finally, soil moisture content may also influence sediment consolidation. Variation(s) in the moisture content within sediment typically result in consolidation when “water is removed or swelling when water is added” (Andrews 2006:473; see also Lambe and Whitman 1969 and Moeyersons 1978). Andrews cautions that researchers should not view sediments as static, but rather that they operate as “fluid bodies” through which archaeological materials may “float, sink, or glide” (Andrews 2006:473).

In addition to issues relating to artifact displacement, sediment consolidation can also influence artifact condition, composition, and alteration. Lithic artifacts subjected to compressive forces are susceptible to fracture or breakage in sediments and variables such as gravel size within the sediment load may influence the regularity of breakage events (Eren et al. 2011). Therefore as sediment consolidation increases, one may also presume an increased potential for gravels within the sediment matrix to modify lithic edges in such a way that they “might be interpreted by lithic analysts as cultural retouch” (Eren et al. 2011:203). However, Eren (et al. 2011) has examined the effects of sediment consolidation on artifact morphology, and has found that sediment consolidation does not lead to the formation of retouched assemblages. In the
experimental simulation, pressure was applied to sediments containing three distinct gravel sizes in which replicated stone flakes were “suspended”. While the incidence of retouch on flakes was minimal, the creation of bend fracture flakes “did occur with some regularity” in medium to large gravel sizes (Eren et al. 2011:2112).

Eren (2011) acknowledges the occurrence of bend break flakes from proposed pre Clovis lithic assemblages, and suggests that the deposits from which these assemblages occur (e.g. alluvial sand, or colluvial clay with little to no gravel) exhibit far less compressive stresses than were examined experimentally. Based on the results of this study, therefore, bend break flakes are not likely to have been formed as a result of sediment consolidation (Eren et al. 2011:212).

However, it is of interest that the alluvial clay terrace at Topper represents a fining up sequence whereby larger particle sizes are present within the deeper deposits at the site. Therefore, it is reasonable to hypothesize that bend fracture flakes might occur in greater numbers from the deeper deposits that contain larger gravel sizes than the higher strata that contain lesser amounts and smaller gravel sizes.

*Thermal Stress*

Lithic materials are susceptible to a number of alterations that form as a byproduct of thermal stress. Thermal stress refers to the strain in a body or structure due to inequalities of temperature. Fracture or breakage of lithic items subjected to heat is typically the result of thermal stress, and occurs when a portion of the material becomes differentially warmer or cooler than another resulting in an unequal rate of expansion or contraction (Luedke 1992).

In lithic materials, raw material homogeneity, stone morphology (size and shape), and thermal conductivity are the attributes most vulnerable to alteration by thermal stress (Rasic 2004:118). Raw materials that have high coefficients of thermal expansion will exhibit greater
frequency fracture due to thermal stress. Quartz is one raw material that has a high coefficient of thermal expansion, and because chert is composed primarily of microcrystalline quartz, it is considered to be highly susceptible to thermal stress (Luedke 1992). Thermal stress also acts to reduce the tensile strength of stone, making it a greater risk to postdepositional breakage.

The size of lithic materials also influences factors of thermal stress. Lithic items that are large exhibit greater risk of thermal stress because portions of the lithic body may heat or cool more (Rasic 2004). As such, one may hypothesize that smaller lithic items such as flakes may exhibit less susceptibility to thermal fracture than larger blocky fragments as the heating and cooling is more homogenous throughout the specimen. Moreover, the amount of heat energy absorbed by a lithic item is influenced by its thermal conductivity. Lithic materials with a greater ability to conduct heat are less likely to be subject to thermal stress fracture than those that have lower conductivity thresholds.

Thermal stress induced fracturing in lithics can take a number of forms including large blocky/angular fragments, potlid fracturing, or surface crazing. Blocky or angular fragmentation of lithic materials typically occurs when stone is heated so rapidly that it explodes into multiple fragments (Purdy 1974). There is a correlation between the release of pressure in heated lithics and the presence of water within the internal structure of the materials. If water is present within a lithic body, the water may be converted to steam as it reaches a critical threshold. The subsequent continual buildup of steam within the lithic body is capable of generating internal expansion thus shattering of the material. Rasic (2004) suggests that in cases where thermal stress results in the detachment of angular debris, subsequent detachments typically lack points of applied force or compression rings.
Another attribute produced by thermal stress is potlidding. A pot lid is a plano-convex flake removed from a larger lithic body as the result of differential expansion and contraction when the lithic is exposed to heat (Ahler 1983). Pot lids exhibit a circular concave scar or pit on the surface specimen with no compression rings or points of applied force. Thermal fracturing of lithic materials can also produce very fine non-linear cracks on the surface of lithic items. These cracks are referred to as crazing (Ahler 1983). Like potlidding, crazing is also another byproduct of differential heating and pressure release. Experimental studies have found evidence of crazing among other forms of thermal fracturing during post fire field observations (Benson 2002; Lentz 1996).

Rasic identifies three mechanisms that can cause thermal stress in archaeological settings (Rasic 2004). These mechanisms include insolation, natural wildfire, and human-controlled fire features. Insolation is the heat created from solar radiation and is conditioned by a variety of microclimatic variables. Insolation affects lithic materials by the rate at which changes in temperature cause fracture in rock masses. Insolation includes the processes relating to the heating and cooling of lithic surfaces. Expansion and subsequent contraction of lithic surfaces heated by the sun can act to destabilize the bonds along the granular boundaries of lithic materials. Over time, this process can lead to the flaking of lithic surfaces and rock fragments. Since many of the processes relating to insolation were covered above (e.g. freeze thaw), I focus the remainder of this section on mechanisms relating to wildfire and human-controlled fire features.

Wildfires are an unintentional form of lithic alteration that can affect lithic assemblages on nearly all landforms (Johnson 2003). Fire-induced change in lithic materials is a complex process and depends on a combination of variables including raw material type, morphology,
orientation, surface position, fire intensity, fire duration, and post-fire cooling rate (Johnson 2003). The effects on lithic materials from wildfire include breakage, spalling, crenulating, potlidding, microfracturing, pitting, bubbling, bloating, discoloration, adhesions, altered hydration, and weight and density loss. It is important to note that some of these attributes such as discoloration may not be visible, as they may have undergone weathering and subsequent patination in the soil following thermal alteration. However, significant thermal alteration of lithic materials that have been subjected to the effects of wildfire are typically limited to within the top 10cm of the “burn level”, and surface artifacts tend to exhibit greater degrees of alteration than those buried in significant subsurface contexts. Thermal alteration that occurs on lithic materials as a result of wildfires typically is not uniform, with the potential for temperatures to rise and fall sharply depending on fire behavior and fuel type/loading (Buenger 2003). Most researchers agree that the higher the fire temperature, the greater the severity of alteration.

The majority of archaeological literature concerning the thermal alteration of lithic materials involves the intentional heat treatment of stone during prehistory, and research has been conducted to assess a number of issues related to thermal alteration including intentional versus unintentional alteration (Anderson 1979), flaking quality (Crabtree and Butler 1964) and temperature thresholds required for specific changes in the raw material properties. Humans can intentionally alter (heat treat) lithic materials to aid control over flake detachment during the lithic manufacture process, or lithic materials can undergo unintentional thermal alteration if raw materials are discarded near a fire pit or hearth (Pevny 2012). In an experimental simulation study to replicate the production of prehistoric stone tools, Crabtree and Butler (1964) found that heat-treating lithic materials prior to the manufacture process resulted in enhanced flaking qualities. Purdy (1974) conducted a comprehensive study on the effects of thermal alteration on
lithic materials that demonstrated that there are specific temperature thresholds at which various changes will occur in the fracture properties of specific cherts. When chert is heated to temperatures ranging from 100–150°C, free water will evaporate from the pores and cracks within the lithic body (Purdy 1974). If heated slowly and maintained between temperatures of 350–400°C, desirable changes will occur in the fracture properties of chert. Such changes many include color change, increased luster and reduced tensile strength (Purdy 1974). Research suggested that if lithic materials are heated too rapidly, or above a critical temperature threshold, fracture (thermal shock) will occur, resulting in debris attribute patterns consistent with those that occur as a byproduct of natural wildfires.

Purdy observed that the color change that occurs as a result of thermal alteration is due to the “presence of minute amounts of iron” held within the lithic material at the time it is heated, and that such change typically occurs at lower temperatures than required to increase chipping ease (Purdy and Brooks 1971:323). Tests undertaken to examine the effect of thermal alteration on lithic tensile strength found a reduction of 45% in the tensile strength of heated samples compared with unheated lithics (Purdy and Brooks 1971). The reduction in tensile strength of thermally altered lithics is often attributed to heat treatment allowing a fracture to propagate across rather than around the microcrystalline quartz grains within the lithic material (Purdy 1974).

**Stress Release Weathering**

Another form of stress related weathering is stress-release weathering. Although not often considered in archaeological studies, stress-related weathering involves the release of compressional stresses that are active on a body of lithic material at depth when the weight of overlying sediment is removed by erosion. The release of pressure on lithics at depth can result
in fracture and breakage patterns on detached pieces that could resemble the attributes of some lithic reductive technologies

_Trampling_

Trampling refers to treading, walking, or stepping upon lithic materials by prehistoric peoples or animals. Archaeologists and lithic analysts are most interested in how trampling affects the modification, damage, or vertical displacement of lithic artifacts (McBrearty et al. 1998). Trampling is often considered as a causal mechanism for the unintentional production of flake edge modification in prehistoric lithic assemblages (Gifford-Gonzalez et al. 1985). Most studies of human trampling involve the comparison of experimentally replicated assemblages to the archaeological assemblages that are thought to have undergone prehistoric trampling. The variables that are most likely to influence artifact breakage during trampling include substrate, raw material type, and artifact morphology. Artifacts that undergo trampling over coarse-grained substrates are thought to exhibit a greater degree of edge damage than those that undergo treadage on fine-grained substrate (Flenniken and Haggerty 1979). However, McBrearty et al. (1998) found that edge modification on lithic artifacts that have undergone trampling on fine-grained sediments can also be severe (McBrearty et al. 1998). Moreover, some lithic raw materials are harder than others and therefore will respond differentially when pressure is exerted by trampling. Artifacts that are thin and that are oriented horizontally are more susceptible to breakage than artifacts that are bulkier and inclined. One may also expect flakes that are curved as opposed to flat to exhibit higher occurrences of breakage. When breakage does occur on trampled lithic assemblages, McBrearty et al. (1998) find most damage to consist of “irregular, abrupt or alternate edge modification, the blows often directed at nearly right angles to the edge, rather than delivered oblique to the edge as in normal retouch” (McBrearty et al. 1998:109).
The recent discovery of bend and radial break flakes at a number of proposed pre Clovis assemblages has generated interest in the prospect of trampling as a causal mechanism for the production of such assemblages. Jennings (2011) conducted an experimental study to compare replicated bend break flakes to breaks produced incidentally during bifacial core reduction and those produced by trampling. Flakes were trampled on a “hardened silty-clay soil surface” and “all breaks larger than 1 cm in length were subsequently analyzed” (Jennings 2011:3). The results of this study found significant differences in the break types produced when the trampling assemblage was compared with the flakes that were intentionally fractured (Jennings 2011:5). Trampling appears to produce a “near absence” of radial break flakes, and individual flakes trampled directly on the ground surface broke only by bending fracture with “no evidence of impact” (Jennings 2011:7). Jennings concludes that high occurrences of radial break flakes can be used to differentiate “intentional breakage from trampling damage”. He suggested that, “to distinguish intentionally fractured flakes from trampling damage, the ratio of radial to bend fractures should exceed 3to20” (Jennings 2011:7).

Apart from breakage and edge damage, experimental studies have shown that trampling can lead to vertical displacement of lithic artifacts from their original context. For example, artifacts that have undergone trampling in sandy sediments are more prone to exhibit vertical displacement that those tread on in more compact or clayey sediments (Gifford Gonzalez et al.1985). These findings imply that objects tend to penetrate deeper in loose sediments as a result of trampling. However, artifact morphology such as size and weight also influences an artifact’s susceptibility to vertical displacement. Studies have shown a positive correlation between artifact weight and downward migration of artifact’s (Moeyersons 1978). In contrast, Gifford-Gonzales (et al. 1985) found that weight-dependent sorting as a byproduct of trampling typically only
occurs within the top 30cm of the soil profile, and more research is needed to fully understand the dynamics between trampling, artifact size, and vertical displacement (Gifford-Gonzalez et al. 1985). Other studies cite sediment moisture content as a potential variable that influences vertical displacement during trampling (Eren et al. 2010). Because saturated sediments are “weaker” and more vulnerable to “deformation or applied stress,” it is expected that lithic artifacts in saturated environments will exhibit greater vertical displacement than those exposed to drier ones (Eren et al. 2010).

Fluvial processes

Fluvial processes refer to the movement of material agents generated by the activities of rivers, streams and associated flow. Fluvial processes play an important role in archaeological site formation, preservation, and disturbance episodes. Research by Waters (1988:479–491), has shown that archaeological materials may be preserved through rapid burial due to fluvial action, redeposited in secondary context, or destroyed as a result of erosion. Therefore, it follows that lithic materials in fluvial settings may undergo a variety of postpositional disturbances because of fluvial action.

Petraglia and Potts (1994) recognized a number of ways by which archaeologists have attempted to evaluate the effects of water flow on archaeological assemblages. Water flow can modify, or affect artifact orientation, cause rounding, and result in size sorting, and even the spatial distribution of lithic assemblages (Petraglia and Potts 1994). The primary spatial association and “composition” of lithic assemblages are more prone to modification in high-energy environments. Such modifications may occur as lithic materials collide under high-energy conditions. Lithic assemblages that exhibit high degrees of similarity in long axis orientation such as “parallel or criss-cross patterns” are also considered to form because of “flowing water”
and are an indicator of the direction and intensity of flow (Petraglia and Potts 1994:230; but see also Issac 1967). Likewise, variation in artifact inclination can depend on fluvial processes. In most cases, lithic specimens that are inclined at steeper angles reflect greater flow velocity (Petraglia and Potts 1994).

The amount of time between artifact discard and subsequent burial can influence the degree of artifact movement. Petraglia and Potts (1994) found a direct correlation in the degree of artifact movement and the amount of time the artifact has been exposed on the ground surface. Assemblages exposed on surfaces for longer periods prior to burial are more likely to undergo movement and disturbance than those that are buried rapidly. Sediment grain size can also inform about the energy contexts under which a lithic assemblage may have been modified. Coarse-grain sediments that contain medium to large-size cobbles and pebbles were likely deposited under high-energy environments, whereas silt and clay deposits typically signal deposition by low-energy. Moreover, research suggests that there is a correlation between water flow velocity and the morphology of transported materials (Petraglia and Potts 1994). Accordingly, slow to moderate flow rates have a greater impact on the movement of smaller specimens from an assemblage whereas larger items are typically transported only under the highest energy conditions.

Taking these conditions into account, Petraglia and Potts offer the following as attributes consistent with a lithic assemblage that has undergone little to no modification by water flow: “Burial in clay or some other fine-grain sediments, no evidence of preferred orientation of long axis specimens, no evidence for differential size clustering of lithic items by size or direction, and no evidence for surface or edge rounding” (Petraglia and Potts 1994:236). By contrast, an assemblage modified by water flow should exhibit all or some of the following: “deposition in
sandy sediments in a high energy setting”, artifacts that exhibit reorientation of the long axis and that are size sorted such that large items are closer, and small items are further from the place of origin, evidence for edge rounding and non-cultural retouch modification along artifact margins (Petraglia and Potts 1994:236).

**Avenues of Research to Evaluate Lithic Taphonomy**

*Modification and lithic micro wear research*

Artifact context is important when conducting lithic micro wear research. An understanding of taphonomic processes that affect and alter lithic materials once they enter the archaeological record is important, as sometimes damage resulting from post depositional processes can mimic patterns of cultural use. Interpretations of stone tool use are typically determined based on trace microwear analyses of existing archaeological assemblages as well as from tool assemblages that have been experimentally produced. According to Pevny (2012), to make such interpretations it is necessary to have an understanding of how stone fractures, how stone interacts with bodies in motion (tribology), how stone is affected by post depositional processes (e.g. trampling, thermal alteration.), and how it is affected by intentional human use. Each of these processes can be interpreted through microscopic analysis, specifically through high (100–500x) and low magnification. Low magnification (10–70x) is typically employed to examine the shape and size of prior modification detachment scars whereas high magnification is employed to examine evidence of micro-fracture, polish, and striations.

Post depositional processes can obscure evidence of cultural modification by “altering artifact surfaces, introducing damage that resembles human-induced tool use-wear, or by destroying evidence of use-wear” by abrasion or weathering (Wiederhold and Pevny 2014:9). According to Pevny (2012), attributes produced as a result of postdepositional trampling include
bending fractures and L and V shaped fractures. Moreover mechanical damage on flake edges exhibit crushing or abrasion, bright spots, and multidirectional striations. These flake removals are also typically less than 2m from the flake margin, and are randomly oriented (Wiederhold and Pevny 2014).

Artifact Refit Research

Lithic refit analysis can be used to assess site integrity, specifically as it relates to the potential for post depositional vertical and horizontal displacement of artifacts across the site. Refit analyses of archaeological assemblages are beneficial as they deal with the relationship between the spatial configuration and physical properties of lithic artifacts. A recent study by Miller (2010) found eleven refits among a sample of 16,000 lithic artifacts from the hillside portion at Topper. Miller found a maximum horizontal distance of 8 cm between refitted artifacts from Clovis contexts in this area, and used his findings to support the notion that little post-depositional activity has altered the integrity of the Clovis deposits in some locations of the hillside. In another study, D. T. Anderson (2010) conducted a refit analysis of lithic materials recovered from a four by four m block excavation to the north of the lower terrace excavation at the base of the hillside slope. The results of this analysis identified more than 300 individual lithic artifacts that refit. Moreover, few refits were found to cross-cut stratigraphic levels, with most occurring on a common surface. For the present study, refits that are identified will be documented and further examined with regard to their spatial association with other artifacts within the site grid.

River–stained Cortex Research

Lithic material(s), when submerged in or subjected to fluvial activity for an extended period, may become stained. The cortex on unmodified Coastal Plain chert cobbles is typically
chalky white/grey a result of terrestrial patination. By contrast, chert items from underwater contexts become stained brown over time. Therefore, in the Savannah River Valley, chert items recovered from underwater and terrestrial environments have been affected differently and their visual appearance can be used to interpret the environmental conditions it has been exposed to. The degree of river staining is dependent upon the length of time of submergence, as well as the chemical properties of the water and raw material. As such, the presence of river–stained cortex on lithic artifacts is an indication that the piece in question, prior to detachment, was at some point submerged, and possibly “quarried” from the river. Although no experimental studies have been conducted to assess the amount of time required for river staining to form on Allendale Coastal Plain chert from Topper, the potential exists that such formations could take some time to develop. Future studies are needed to evaluate this process in greater detail.

Recent studies by Miller (2010) and D. T. Anderson (2010) have identified the presence of river staining on at least some artifacts recovered from Clovis and Holocene contexts at Topper. The occurrence of such items from these deposits implies that the chert was quarried from the river prior to being reduced onsite during lithic manufacture episodes. The presence of river–stained cortical debitage from known archaeological deposits, combined with the absence of such materials from deeper strata, could be one indication of site integrity. At some point prior to the Clovis occupation at Topper, the Savannah river down-cut its channel, exposing chert to the abrasive nature of the river. Because this chert had yet to be exposed or stained by the river, it was not accessible to any potential pre Clovis peoples that might have been occupying the site at this time. Whereas Holocene and Late Pleistocene Clovis peoples had at least two sources (terrestrial and river) of chert at their disposal for tool production, earlier occupations were
restricted to the terrestrial outcrop. Therefore, the absence of river–stained cortex on artifacts, below Clovis contexts, could be indicative of differentiation in quarry behavior through time.

**Prior Lithic Analysis of the Topper Assemblage: King (2012) Analysis**

From 2009–2011 King examined a suite of lithics and lithic debris recovered from six 1m x 1m columns as part of an MA thesis (Figure 5–20). Her study represented the first systematic examination of the reported pre Clovis assemblage at the site. King selected three of the six units because they had been excavated from the ground surface to the top of the clay Pleistocene Terrace, and reflected a “complete stratigraphic profile” (King 2012:65). This protocol was important for presenting the vertical distribution of debitage from the deposits, which were examined to evaluate “the stratigraphic integrity of the site” (King 2012:43). The units King selected for analysis include the NE and NW quads of unit N246E138 and the NE quad of N246E136. Three additional 1m x 1m units were also selected, and included materials excavated from the top of the Pleistocene Terrace and continued into this older material.

The goal of King’s research was to determine whether the Clovis and potential pre Clovis assemblages at Topper exhibited similar distributions of debitage attributes, and therefore reflect the use of similar technological strategies in the manufacture of stone tools. According to King (2012), the study was guided by the assumption that if the debitage patterns among the Holocene, Clovis, and potential pre Clovis assemblages are similar, then “the probability is very low that the pre Clovis assemblage has been subjected to displacement” (King 2012:42). By contrast “if the patterning of debitage is dissimilar then there is a greater probability that the pre Clovis assemblage was either displaced or created using alternative reduction technologies” (King 2012:42).
Figure 5–20
Planview map of Terrace excavations showing units selected by King for her 2012 MA thesis.
To evaluate the similarity between the Topper Clovis and pre-Clovis assemblage at Topper, King employed mass analysis, Sullivan and Rozen’s interpretation-free analysis (IFM), and artifact attribute frequency analysis. Mass analysis, a form of aggregate analysis that examines the size distribution of the debitage sample, was used to analyze the assemblage using non-technological criteria, and to subdivide the assemblage prior to making interpretations regarding the technology used to create it (Shott 1994). Individual artifact attribute analysis was employed to examine questions regarding reduction stage and manufacturing techniques.

The results of King’s study demonstrated that small incomplete flakes and small debitage consistent with bifacial manufacture strategies were present in Pleistocene – age deposits at Topper (King 2012). However, these artifacts were found in deposits identified by Waters (et al. 2009) as unit 2b, and consist of gravel filled chute channels thought to have been deposited when the Savannah River flowed as a braided stream system. (King 2012:130). As such, these findings may indicate the presence of “considerable disturbance in the Pleistocene archaeological record at Topper” (King 2012:131). The occurrence of flakes in the older deposits could reflect evidence of the bioturbation and displacement of smaller flakes from the overlying cultural deposits, or their presence could reflect the formation or introduction of flakes as the result of fluvial processes. King (2012:131–134] subsequently developed two contrasting hypotheses to account for the occurrence of archaeological materials in the Pleistocene deposits at the site. These are presented below.

1.) “There was no occupation at the Topper Site prior to the arrival of the Clovis populations. If this hypothesis is correct, it would mean that the materials recovered from within the older Pleistocene Sands and Pleistocene Terrace sediments at Topper are likely the result of
natural processes such as bioturbation, freeze thaw action, erosion and deposition from stream flow”.

2.) There was a pre Clovis occupation at the Topper Site. Moreover, the patterns of debitage distribution are different for the Pleistocene Sands levels because the pre Clovis occupants were using a different manufacturing technique, thus leaving behind a different assortment of debitage.

The results of King’s study demonstrate the presence of cultural flakes beneath Clovis bearing deposits at the site. These flakes were found to possess the same or similar attributes as the debitage recovered from the Holocene Terrace. Barring any post depositional disturbances, these findings would tend to support the proposition that these flakes were also produced using stone tool production episodes rather than by natural processes. One important contribution of the study was the identification of stone tools from pre Clovis contexts at the site.

It is important to note that the analytic protocol employed in King’s study called for the use of lithic attributes most common with conchoidal fracture as a means to identify cultural flakes. These attributes include at minimum a striking platform, and interior surface with features consisting of compression rings and a bulb of force. Goals of the project did not determine as to whether the attributes observed on flakes could have been produced as a result of bending or compressive forces. Therefore, it seems essential that any study geared toward distinguishing whether Clovis and potential pre Clovis occupations at Topper utilized different manufacture techniques must consider the technological byproducts that can form as a result of all lithic manufacture strategies. The current study will evaluate the Topper Pleistocene assemblage in detail, and will serve as a test to evaluate which of King’s two hypotheses is more plausible.
Each of the taphonomic processes discussed in this chapter have the potential to alter or modify existing archaeological assemblages or create lithic materials that could be misinterpreted as the byproducts of human lithic manufacture. In the following chapter a research design is proposed to account for the taphonomic processes that might be active at the Topper Site. The goal of this study is to determine whether or not the lithic items from the proposed pre Clovis assemblage resulted from natural taphonomic processes, or alternatively represent human agency.
CHAPTER VI

RESEARCH DESIGN

This chapter presents the research design used to examine the lithic assemblage at the Topper Site. I begin by summarizing the goals of this analysis, followed by a brief review of the methods and results of prior lithic analyses of the pre Clovis assemblage. This discussion is followed by an outline documenting how the research sample was selected, and what criteria were employed in choosing the attributes for analysis.

Research Goals

Excavations undertaken at the Topper Site have revealed evidence of chipped stone tools that span the entire known culture chronology for the southeastern U.S extending back ca. 13,500 years. Each of these cultural components ranging from Mississippian through Clovis made use of the local Allendale chert outcrop, implementing similar bifacial reduction technologies in the manufacture of chipped stone tools. The presence of cultural materials beneath the Clovis deposits consisting of conchoidal flakes (King 2012) and bend breaks typically considered to be byproducts of bipolar reduction suggests an older occupation at Topper. This assemblage is referred to as the Topper pre Clovis assemblage.

The stated goals of this study are to 1) determine the origin of the lithic materials identified as conchoidal flakes from the Topper pre Clovis assemblage; 2) test the role of human agency in the manufacture of the materials preliminarily identified as bend break flakes and 3) provide a comprehensive description of the lithic assemblage that will enable a better understanding of the technological strategies of tool production at the site.

Most issues with claims for pre Clovis assemblages have involved problems with one of three classes of data: dating, context, and artifact status. Extensive studies at Topper have been
undertaken to establish the geochronology, resulting in a well defined geological context for the assemblages, and a somewhat less secure chronological framework (Waters et al. 2009). This dissertation addresses the material remains found in the deposits, and focuses on problems of context and artifact status.

Contextual problems deal with goal 1, determining the origin of flakes from the Topper assemblage. Natural processes such as bioturbation, colluvial redeposition, and fluvial activity can redeposit existing archaeological assemblages, and it is necessary to distinguish whether such processes occurred onsite in the past, and the degree to which they may have affected the spatial integrity of the Topper assemblage. The second goal of this study deals with problems of artifact status, and specifically whether bend break flakes from the Topper assemblage are byproducts of human agency or are the direct result of natural weathering processes such as freeze/thaw, hydric forcing, or sediment consolidation. These natural processes can create lithic items that may exhibit attributes that mimic those evident on cultural artifacts. Therefore it is essential to establish and isolate the attributes consistent with lithic manufacture from those that form by natural processes. The third goal of this study entails artifact attribute analysis. If any spatio–temporal differences in the composition of artifacts exist at Topper, the attribute analysis can be used to identify such differences and make interpretations about the technological strategies employed in their production.

**Methodological Framework**

The methodological framework developed for this dissertation incorporates multiple objective analyses. These analyses include 1); individual lithic artifact attribute analysis of the Clovis and pre Clovis assemblages recovered from the site’s three stratigraphic units (Holocene/Late Pleistocene Colluvial Sands, Pleistocene Alluvial Sands, Pleistocene Alluvial
Terrace); 2), trace micro wear analysis of a sample of artifacts recovered from the Clovis and Topper pre Clovis assemblages; 3), experimental archaeology consisting of natural mechanical weathering experiments of Allendale chert and subsequent comparison of the lithic byproducts to those items recovered from the deposits at Topper; and 4), spatial analysis, size grade analysis and cortical analysis conducted to interpret site formation processes and site integrity.

Research Sample

This study examines lithic materials recovered from 16 2m x 2m units of Holocene and Pleistocene Sands, and 14 1m x 1m units from the clay Pleistocene Terrace that underlie the Pleistocene Sands at Topper (Figures 6–1 and 6–2). The 16 2m x 2m units include materials that derive from Early Archaic deposits to the top of the alluvial clay Terrace. The upper sediments of these units were excavated in 10cm arbitrary levels. Once Clovis deposits were encountered, or at 65cmbs, excavation commenced in 1m x 1m quads and in 5cm arbitrary levels. The 16 2m x 2m units derive from four separate but ultimately contiguous excavation areas of the site. These include units from the 2002–2003 5m x 9m block excavation, the 2009–2012 excavation north of BHT17 (Northern Terrace excavation), the 1998–2000 4m x 8m block excavation, and the 2010 4m x 4m block excavation (Figure 6–2).

One important component of this analysis was to select units that represent complete stratigraphic profiles from Early Archaic deposits to the base of the Pleistocene Terrace. Therefore, the 14 1m x 1m Pleistocene Terrace units selected for analysis all derive from contexts that lie immediately beneath the corresponding units from the 2m x 2m sample. This allows for the examination of the vertical and horizontal distribution of lithic materials from discrete units in the block, and is important for evaluating potential disturbance between or within individual occupational episodes. Of note, three of the 1m x 1m Pleistocene Terrace units
Planview map of Terrace excavations showing 1m x 1m Pleistocene Terrace units selected for analysis in for this study.

Figure 6–2
Planview map of Terrace excavations showing 2m x 2m units selected for analysis in for this study. The area highlighted in black was previously examined and reported by King (2012). Three Pleistocene Terrace units examined by King were also examined for the present study. These include units N246 E140 NE and SE and N246 E142 SW.
selected for analysis overlap with units analyzed by King. These include units N246 E140 NE, SE, and N246 E142 SW quad and are depicted in Figure 6–1.

All Pleistocene Terrace units selected for analysis were excavated in 5cm arbitrary levels. The sample selected from the Pleistocene Terrace represents all of the 1m x 1m units excavated to date. Four partial Pleistocene Terrace units have also been excavated, surrounding BHT 17. However, these partial units were excavated in 10cm levels rather than conventional 5cm levels. The considerable differences in size among these units makes problematic any comparison with the full 1m x 1m units. Therefore, no partial unit was examined in this study.

The lithic materials selected for analysis in this study include: 1) three dimensionally piece plotted items from each level within the site grid, and 2) all lithic materials recovered from the 1/8 inch screen mesh. Accordingly, all lithic items 2.5cm in diameter or greater were mapped when possible. To date this consists of nearly 10,000 items from the alluvial floodplain portion of the site. This protocol was conducted regardless of whether visible evidence for cultural flaking was identified on the specimen in question, and therefore does not make predetermined infield assumptions regarding the role of human agency in the production of each piece plot. Furthermore, the procedure allows for the spatial arrangement of all materials above the stated size grade within the assemblage to be assessed. Attribute analysis in the lab enables the development of interpretation free artifact categories from which the spatial arrangement of each category may then inform about assemblage composition through time.

**Lithic Analysis**

*Debitage Attribute Analysis*

Debitage attribute analysis is designed to identify attributes that distinguish culturally produced flakes from those specimens that may form as a result of natural or taphonomic
processes and also to establish if any variation exists in lithic technology through the vertical profile at the site. Technological attributes considered for this analysis include the presence or absence of striking platform, bulb of force, compression rings, ripple marks, number and direction of removal scars, flake condition (complete, proximal, medial, distal), presence or absence of modification, thermal alteration and river staining. The incidence of cortex on lithic specimens was recorded to document the nature and extent of reduction. In addition to these technological attributes, morphological attributes were also recorded and included measures of flake length, width, thickness, and weight.

Sullivan and Rozen’s interpretation free model was employed to characterize the nature of the lithic assemblage. Their method incorporates three dimensions of variability, each with two outcomes (Sullivan and Rozen 1985). These variables include a single interior surface, a point of applied force, and intact margins. For the present study, two additional attributes of variability, bulb of force and compression rings are added to distinguish between specimens that have interior surfaces resulting from mechanical weathering, and those produced through force initiation. This model results in six debitage classes. Figure 6–3 presents a flow chart showing how each debitage category was determined, a modification from the flow chart presented in Figure 5–15 to accommodate the Topper materials. The analytic framework was used to document assemblage variability between the Clovis and pre Clovis assemblage deposits, and to determine the role of human agency. The six debitage classes are presented in Figure 6–3 and are defined as follows:

**Pebble/Cobble**– Lithic specimens that lack a discernible interior surface, compression rings, bulb of force, point of applied force and intact margins. For the purpose of this study pebbles and cobbles can be any round, subrounded, or subangular lithic item that does not
Flow chart showing debitage categories used in Interpretation Free Analysis. Modified from Sullivan and Rozen (1985:759).
exhibit an attribute consistent with a detachment struck from a core. The Wentworth scale provides a good means by which to classify lithic objects by size. By definition, pebbles range in size from 4-64 mm, whereas cobbles range in size from 64-256 mm. Two sub-categories of pebbles/cobbles are defined based on material, and include cortical and quartz.

**Amorphous debris**—Lithic specimens that have a discernible interior surface, yet lack compression rings, bulb of force, point of applied force and intact margins.

**Debris**—Lithic specimens that have a discernible interior surface and compression rings, but lack a bulb of force, point of applied force and intact margins.

**Flake fragment**—Lithic specimens that have a discernible interior surface, compression rings, and bulb of force, yet lack a point of applied force and intact margins.

**Broken Flake**—Lithic specimens that have a discernible interior surface, compression rings, bulb of force, and a point of applied force, yet lack intact margins.

**Complete Flake**—Artifacts that have a single interior surface, compression rings, bulb of force, a complete or partial striking platform, and intact margins with a clear point of termination.

For the purpose of this study, artifacts of potential human agency must have at least one interior detachment face that has been released from an objective piece, and must exhibit force lines (compression rings) that emanate from the direction of a point of applied force. These lines, or compression rings, are evidence of applied force resulting from flake initiation, propagation and detachment, and may be used to distinguish lithic pieces that have been detached by weathering and/or taphonomic fracture agents, from those that are a product of force. Lithic materials that exhibit only a detachment face, and that do not have evidence of lines of force are classified as naturally formed debris (amorphous debris). A complete flake has a point of applied
force and intact margins, whereas flake fragments, broken flakes, and other debitage lack such attributes (Andrefsky 2005:18). Barring relocation or downward movement of humanly created materials, if people were exploiting the locally available chert quarry at Topper prior to Clovis, then I expect similarity in assemblage composition and frequency of debitage categories for the Clovis and pre Clovis deposits. By contrast, if peoples were not present at Topper prior to the Clovis occupation, then barring any downward movement or displacement of humanly produced artifacts from elsewhere, and holding reductive technology constant, I expect no similarity in assemblage composition and frequency of debitage categories for Clovis and pre Clovis deposits. Furthermore, the attributes found on materials from these lower deposits should consist primarily of amorphous debris that could result from natural weathering.

Lithic Analysis: Flake Formation

In an initial analysis of the pre Clovis deposits at Topper, King (2012) examined attributes of flake types known to occur as a byproduct of biface manufacture, and the research design for her study assumed that “each of the populations occupying the Topper Site utilized the same technology” (King 2012:42). However, other lithic tool production technologies may produce artifacts that have attributes that are unlike those produced as a result of biface manufacture. Goodyear (2005) contends that the Topper assemblage was produced using a bipolar technology, whereby wedging and bending initiation were employed to produce compression and bend fracture flakes. Goodyear further asserts that debitage from such manufacture may produce attributes that are unique and inconsistent with traditional biface reduction trajectories. In contrast, Waters (et al. 2009) assert that the pieces” that comprise the Topper assemblage could have also been produced by natural processes such as thermal fracturing or physical fracturing during stream transport.
It is essential in this study to determine the technology or technologies employed in the production of stone tools at Topper, as well as the specific techniques applied in manufacture. In stone tool production, technology refers to the sum total of manufacturing knowledge necessary to produce a given tool. This includes the transmission of information gained with regard to artifact form and style, and turning them into lithic implements of use. Technology is thus the formal design strategies applied in carrying out a specific manufacture trajectory. Associated with technology is technique. Technique is the application of a given technology, and refers to the mechanism(s) by which applied force, initiation, propagation and termination are carried out, as well as the implements used for lithic detachment. As such, technology may be said to be of the mind, whereas technique is in the hand.

For this study, Cotterell and Kamminga's (1987) model of flake formation is used to assess lithic technology, and to determine the techniques applied in stone tool production at Topper. Technological strategies of lithic tool production considered for this analysis include: biface and core flake manufacture by conchoidal hertzian flaking; bipolar core reduction by compression flaking; and bend fracture flaking by either bending or compression forces. Because bend fracture technologies result in flakes whose lateral margins may not be intact, it is necessary to distinguish between intentionally produced bend fracture flakes from those flakes that are incidentally broken during biface manufacture. For this analysis, each flake is examined for the presence or absence of breaks, as well as the morphological characteristics of such breaks. Breaks were classified as either bend or hertzian based upon the mechanics of fracture as described by Cotterell and Kamminga (1987). Morphological attributes recorded for breaks include maximum flake thickness, and number of broken margins. Attributes that are consistently identifiable with bend breaks include: points and cones of percussion, incipient
cones, dorsal crushing at the point of impact, wedge shaped fracture lines, and lips or protrusions along the terminal end of a break face on a bend break resulting from bending initiation. If Clovis and pre Clovis peoples were present at Topper, and if they shared the same lithic manufacture strategies, then the expectation is that the same flake types and lithic technologies should occur in both Clovis and pre Clovis deposits. Alternatively, If Clovis and pre Clovis were present at Topper and did they not share the same lithic manufacture strategies, then the composition of flake types in each assemblage should be distinct.

_Lithic Analysis: Stone Tool Analysis_

The lithic assemblage at the Topper Site was classified by tool type. Andrefsky (2005) presented a morphological typology for the classification of all chipped stone artifacts, and the current study incorporated this typology to categorize all stone tools that were mapped from the sample of units selected. The sample was initially divided into two categories, tools and non-tools. Non-tools include unmodified flakes and angular shatter. Categories of tools used for this analysis include biface tools, core tools, and flake tools. The flake tool class was further subdivided into blade tools/ uniface tools and bend break tools. All flake tools must exhibit evidence of modification to be distinguished from unmodified (non-tool) flakes. The morphological typology of stone tools was employed to identify the types of tools that were manufactured or used in specific locations onsite. The methodology is also used to distinguish whether or not there are any differences in technological strategies of tool production through time. If peoples were exploiting the locally available chert quarry at Topper for the production of chipped stone tools prior to Clovis, then there should be evidence for at least one of three types of tools (biface tools, core tools, and flake tools) from the deposits, barring movement or relocation of these items from elsewhere. By contrast, if there is no pre Clovis occupation at
Topper, then it follows that stone tools should not be present in the Pleistocene Sands and Terrace, barring movement or relocation of these items from elsewhere.

If there is evidence for pre Clovis tool production at Topper and if such production is technologically dissimilar to Clovis or later lithic technologies then I also expect dissimilarity in the frequency and types of debitage recovered from these deposits. Similarity in toolkit composition would indicate that 1) either two groups of peoples, separated in time, were using the same technological strategies of tool production and use, or 2) the tools observed were being redeposited from Clovis contexts into deeper strata at the site.

**Lithic Analysis: Trace Microwear and Edge Modification Analysis**

**Trace Microwear Analysis**

Microscopic analyses were conducted to determine whether lithic items recovered from the Pleistocene alluvial sands and Pleistocene Terrace at Topper were a byproduct of human versus nonhuman agency. Trace microwear analysis was employed to examine the Clovis and potential pre Clovis assemblages at Topper, and is used to distinguish between patterns of use and natural taphonomic processes. For this analysis, the location and relationship of flaking and microwear indicators is significant (Wiederhold and Pevny 2014). Experimental studies have shown that different types of tool use can result in different flaking patterns on tool margins, and can be used to identify the “actions that produced the flaking (Odell 1981a, 1981b, 2003; Tringham et al.1974; Vereecken 1980; Shea 1987; Wiederhold and Pevny 2014).

Attributes that are consistent with use include uniform polish and striations identified on the exterior and interior of flake surfaces, and that is restricted to edges and oriented parallel to the lateral margins. Chips and removal scars produced by cultural agents should be patterned, consisting of two or more consecutive removals that are uniform and that occur on the lateral
margin of the flake. Evidence of use on bend fracture flakes should consist of transverse or parallel polish and striations on the flat surfaces of these flakes and have a high degree of polish on the projections at the intersection of the snapped edges. For the purpose of this study, microwear resulting from intentional human use should exhibit a definite pattern of three or more consecutive fractures along a potentially used edge, together with corroborative evidence in the form of polish, striations, or linear features consistent with interaction between bodies in motion.

By contrast, attributes that might indicate postpositional disturbance or trampling include crushing or abrasion of the flake margin, random or un-patterned bright spots, and striations that are multidirectional. Micro-flake removals produced by natural processes should be less than 2m from the flake margin, should be randomly oriented with respect to the flake edge, and should not occur as more than two consecutive parallel removals. Although both natural as well as modern human-induced processes such as bag-wear can result in the occurrence of apparent microwear on lithic items, the present study operates under the assumption that uniformity in patterning of micro-chipping combined with striations serves as the best evidence for microwear resulting from cultural processes.

**Modification**

All artifacts from the Topper assemblage were examined for the presence of macroscopic modification. Modification refers to the alteration of a tool or artifact in such a way as to rejuvenate, enhance, or extend its use-life, or to change it into another tool form. Evidence of modification typically takes the form of flakes or chips from one or more lateral margins of the tool. Andrefsky (2009: 69, see also Andrefsky 2012) has developed an index of modification to distinguish edge modification on tools resulting from human use versus those occurring as a byproduct of natural processes. This method measures the number of segments of an artifact that
have undergone modification. An artifact is placed under a grid with eight sections. The number of segments that show evidence of modification is calculated. Andrefsky has found that edge modification attributed to human use typically occurs within a range of 2–5 segments of the artifact. Artifacts with two or fewer segments or greater than 5 segments of with modification are attributed to natural or post depositional processes. If Modification resulted from intentional human use, such modification should exhibit a definite pattern of three or more consecutive fractures along a potentially used edge and no more than 5 of 8 segments of the tool or flake having retouched or used edges. Corroborative evidence must also be present in the form of polish, striations or linear features consistent with interaction between bodies in motion. If modification resulted from natural processes, such modification should consist of two or fewer or greater than 5 segments of the artifact’s surface having been modified.

The methodological framework offered above allows for the construction of testable hypotheses with regard to the cultural and potential chipped stone assemblages at Topper. Hypotheses pertinent to lithic technology at Topper are presented in Table 6–1 and in Figures 6–4 through 6–6 as flow charts, and are applied to evaluate the role of human agency in the production of lithic materials from pre Clovis contexts at Topper.

Hypothesis:

If there was a pre Clovis occupation at Topper, then evidence of this occupation should be indicated by 1) similarity in the composition of debitage attributes for the Clovis and pre Clovis

Hypothesis: Barring displacement of Clovis materials into the underlying deposits, if people were exploiting the Topper Site prior to Clovis, then I expect the occurrence of one or more lithic categories that meet the minimum definition of human agency from these deposits (e.g., debris, flake fragments, broken flakes, or complete flakes).

Alternative Hypothesis: If peoples were not present at Topper prior to the Clovis occupation, then barring displacement of Clovis materials into the underlying deposits, I expect the pre-Clovis deposits to consist primarily of amorphous debris and other items that could result from natural weathering.

Hypothesis: If Clovis and pre-Clovis peoples were present at Topper and shared the same lithic manufacture strategies, then I expect similarity in the flake types and lithic technologies for both Clovis and pre-Clovis assemblages.

Alternative Hypothesis: If Clovis and pre-Clovis peoples were present at Topper and did not share the same lithic manufacture strategies, then I expect the composition of flake types in each assemblage to be different.

Figure 6–4
Chart showing Hypotheses and Alternative Hypotheses for Interpretation Free Attribute (above) and Flake Formation Analyses (below).
Morphological Typology for Chipped Stone Tools

Hypothesis:
If people were exploiting the chert quarry at Topper for tool production prior to Clovis, then there should be evidence of one or more tool types (biface, flake, or core tools) from the pre Clovis deposits, barring displacement of these items from elsewhere.

Alternative Hypothesis:
If there is no pre Clovis occupation that practiced stone tool production at Topper, then it follows that stone tools should be absent from the Pleistocene Sands and Pleistocene Terrace, barring displacement of these items from elsewhere.

Hypothesis:
If there is evidence for pre Clovis tool production at Topper, and if the associated reductive technology differs from Clovis, I also expect dissimilarity in the interpretation free and flake formation categories between the Clovis and pre Clovis assemblages.

Alternative Hypothesis:
If there is evidence for pre Clovis tool production at Topper, and if the associated reductive technology is similar to Clovis, then I expect that either the two groups were employing the same tool production strategies, or that the tools observed from pre Clovis contexts have been displaced from the overlying deposits.

Figure 6–5
Chart showing Hypotheses and Alternative Hypotheses for Morphological Typology for Chipped Stone Tools.
Hypothesis:
If observed microwear on lithic items from Topper resulted from intentional human use, then evidence of such use should be indicated by a definitive pattern of three or more consecutive fractures along a potentially worked edge, no more than 5 of 8 segments of the tool or flake having retouched or used edges, and corroborative evidence in the form of one or more indicators of polish, striations, micro-chipping, or residue.

Alternative Hypothesis:
If observed microwear or modification on lithic items at Topper resulted from natural processes, such modification should consist of 2 or fewer, or greater than 5 segments of the artifact’s surface having been modified. If postdepositional processes were responsible for the microwear, then such evidence should take the form of crushed margins, and random, un-patterned bright spots, and multidirectional striations.

Figure 6–6
Chart showing Hypotheses and Alternative Hypotheses for Micro – wear and Modification Analyses.
assemblages, 2) similarity in flake types and lithic technologies between each assemblage if peoples utilized the same reductive technologies 3) evidence of one or more chipped stone tool types (bifaces, flake, core) from pre Clovis deposits, 4) microwear patterns that consist of three or more consecutive, uniform detachments along a potentially used margin that also exhibit one or more attributes of polish, striations, or linear features, and that more than two, but no greater than five of 8 segments of a tool or flake having retouched or used margins.

Alternative Hypothesis:

If there was no pre Clovis occupation at Topper, then there should be 1) no similarity in the composition of debitage attributes for the Clovis and pre Clovis assemblages, 2) no similarity in flake types and lithic technologies between each assemblage 3) no chipped stone tool types (bifaces, flake, core) from pre Clovis deposits, and 4) a lack of microwear patterns on lithic items recovered from the pre Clovis deposits.

**Experimental Archaeology**

As part of this dissertation, I implemented experimental archaeology to test the effects of mechanical weathering on chert cobbles. This study was developed to assess whether mechanical weathering agents, acting on a given mass of stone, may affect its internal properties in such a manner as to produce natural detachments that might be mistaken for artifacts of cultural origin. The results of laboratory simulations on various mechanical weathering influences were compared to the attributes of (1) the potential pre Clovis bend break assemblage recovered from the Pleistocene alluvial sands and Pleistocene Terrace at Topper, and (2) a controlled assemblage of bend breaks recovered from stratigraphically intact deposits from off–site contexts. This off–site control assemblage consists of Fort Payne chert and was recovered from alluvial and colluvial deposits from Williamson County, Tennessee at approximate latitude N 35.8650,
longitude W -86.7071. Artifact attribute analysis employed in conjunction with experimental replication studies may help answer questions related to flaked stone taphonomy.

To test the effects of mechanical weathering on chert cobbles from Allendale County, South Carolina, the effects of three variables were examined: air temperature, moisture level and water temperature. The goal was to determine what variables had the greatest effect on the material integrity of lithic bodies. A total of four weathering simulations were undertaken:

1. Freeze/Thaw

   In the first procedure, a cobble was frozen for 12 hours at 25 degrees F, and subsequently left to thaw at 65 degrees F for an equal duration. The cobble was then inspected for the presence of structural fatigue and or micro fractures produced as a result of cryogenic or thermal induced processes. Briefly, if fracture was found to occur, the specimen was collected and examined for the presence or absence of specific identifiable attributes. This procedure was conducted to assess the effect of temperature on a given chert cobble, and the conditions necessary to produce lithic detachments from the parent material. A total of 25 cycles were run for this experiment on an unaltered chert cobble selected at random from the Topper Site. Photographs were taken prior to and subsequent to each freezing and thawing cycle for comparative purposes.

2. Freeze/Thaw/Wet

   In the second procedure, a cobble was frozen for 12 hours, allowed to thaw, and was subsequently immersed in a body of water held at room temperature (65 degrees F) for a period of 12 hours. This process was repeated, and was conducted to assess the effect of moisture content and temperature on a given chert cobble. A total of 25 cycles were conducted for this experiment. The analysis was conducted using an unaltered chert cobble selected at random from
the Topper Site. Photographs were taken prior to and subsequent to each freezing and thawing cycle for comparative purposes.

3. Freeze/Thaw/Wet/Heat

The third procedure was the same as procedure 2, with the exception of the added variable of increased water temperature. Accordingly, a chert cobble was immersed in hot water (120 degrees F.) for a duration of 12 hours, as opposed to that at room temperature prior to having undergone the freeze thaw process. This procedure is conducted to determine if water temperature has any influence on the mechanical degradation of a chert cobble. A total of 25 cycles were run for this experiment. The analysis was conducted using an unaltered chert cobble selected at random from the Topper Site. Photographs were taken prior to and subsequent to each freezing, wetting, heating, and thawing cycle for comparative purposes.

4. Wet/Dry

The fourth procedure is employed to assess the influence of moisture on physical rock weathering. For this test, a fourth cobble was immersed and then dried for a period of 12 hours each, observing the presence or absence of structural fatigue for each hydric cycle. In addition, each chert cobble was weighed prior to and subsequent to each weathering cycle (weighed when wet and when dry), as weight may inform on the occurrence and amount of evaporated water loss. A total of 25 cycles were conducted for this experiment. The analysis was conducted using an unaltered chert cobble selected at random from the Topper Site. Photographs were taken prior to and subsequent to each wetting and drying cycle for comparative purposes. Each of the four procedures was conducted on a single specimen so as to differentiate the process(es) responsible for the greatest extent of observable weathering.
All lithic cobbles were weighed and photographed prior to and after each weathering cycle. Furthermore, if lithic detachments resulted, each specimen was measured, weighed and examined for debitage attribute properties. These items were compared to the attributes of lithic artifacts recovered from the archaeological assemblages at Topper, and to the attributes of bend fracture flakes recovered from the off-site control assemblage. The goal of the mechanical weathering experiment was to assess if specific agents of weathering (temperature and moisture) on chert cobbles can result in the formation of lithic detachments. If so, are there any attributes present that share similar characteristics to and that may be mistaken as cultural artifacts?

Technological attributes examined for detached spalls included the presence or absence of cortex, an interior detachment face, parallel or irregular lateral margins, and presence and number of right angle break faces. Morphological attributes recorded included maximum detachment thickness, and maximum break angle thickness.

If the Topper pre Clovis lithic assemblage is a byproduct of human agency, then I expect that the attributes observed on the experimental weathering detachments to be distinct from, and can be differentiated from, the attributes found on inferred humanly-created artifacts recovered from the Topper assemblage. Such findings would imply a cultural origin for the lithic assemblages at the site.

If the Topper assemblage is a byproduct of natural weathering processes, then I expect the attributes found on the lithic specimens from this assemblage to be indistinguishable from those observed on the detachments produced from the natural weathering experiment. Artifacts of human agency must exhibit at the least a detachment face and lines of force on that face that emanate from a point of applied force. If the Topper pre Clovis assemblage was a product of bend break manufacture, then I expect the attributes of this assemblage to be statistically distinct.
compared to the attributes consistently identified on items examined from the off-site control sample of lithic items that resemble bend break flakes. This control assemblage was recovered from alluvial and colluvial deposits in stratigraphically intact deposits where there is no other indication of cultural activity. If on the other hand mechanical weathering processes were responsible for producing the Topper pre Clovis lithic assemblage, then I would expect the attributes most commonly found on the artifacts recovered from this assemblage to be similar to those observed on lithic detachments formed by the simulated weathering experiments. Artifacts consistent with weathering processes should lack force lines on the interior surface of lithic specimens.

**Site Formation Processes**

Although King (2012) has noted the presence of flakes from strata underlying the Clovis deposits at Topper, the potential exists that these materials were redeposited or reworked from their original position of discard. To determine whether post depositional processes have altered and or redeposited the lithic flakes and tools from the Topper Site, I conducted a series of spatial, refit, cortical, and mass analyses. Hypotheses for these analyses are provided in Figures 6–7 through 6–10.

*Spatial Analysis*

All lithic materials from the Topper pre Clovis and Clovis assemblage were examined to assess their location in relation to one another within the spatial grid at the site. Spatial analyses were conducted to assess if non-random horizontal or vertical patterns exist within the Topper Clovis and pre Clovis assemblages, and to aid in establishing the processes responsible for their location of deposition. For these analyses, I recorded the northing (X), easting (Y), and depth (Z) for each piece of lithic material recovered. I subsequently use Arcscene, a function within
Figure 6–7

Chart showing Hypotheses and Alternative Hypotheses for Spatial Analyses.

Spatial Analysis

Hypothesis:
If the spatial distribution of pre-Clovis items is non-random, without evidence of fluvial displacement or in-situ weathering, then I expect the assemblage to be the product of human agency.

Alternative Hypothesis:
If the spatial distribution of pre-Clovis items is a random pattern throughout the profile, a non-random pattern with clustering only in cracks, or a non-random pattern with evidence of fluvial displacement, then I expect the assemblage to be the product of natural processes.

Hypothesis:
If the spatial distribution of items that meet the minimum criteria of debris is non-random and if it is oriented horizontally with regard to a common surface, then barring fluvial or mechanical weathering processes, the assemblage is considered the product of human agency.

Alternative Hypothesis:
If the spatial distribution of items that meet the minimum criterion of debris is random, or is distributed vertically with regard to the stratigraphic profile, then the assemblage is considered a product of displacement by natural processes.
Figure 6–8
Chart showing Hypotheses and Alternative Hypotheses for Refit Analyses.

**Hypothesis:**
If refits are identified from the pre-Clovis deposits, then barring displacement, I expect examples produced by human agency to be non-randomly distributed.

**Alternative Hypothesis:**
If refits are identified from the pre-Clovis deposits, I expect examples that have undergone natural disturbances to be randomly distributed.

**Hypothesis:**
If two or more lithic detachments that meet the minimum definition of debris refit, and if both items are found on a common surface, then the resulting association is considered evidence of human lithic manufacture.

**Alternative Hypothesis:**
If two or more detachments refit, but do not meet the minimum definition of debris, then the resulting association is considered the product of natural processes.
Figure 6–9
Chart showing Hypotheses and Alternative Hypotheses for Cortical Analyses.

Hypothesis
If the percentage of cortical debris is high or is non-random when observed in stratigraphic association with artifacts that meet the minimum definition debris, then this association is likely the result of lithic production.

Alternative Hypothesis
If the distribution of cortical debris is low or is random, is not sorted by size, and shows no correlation with identified artifacts, then it is not considered a byproduct of lithic production, and may instead be a product of natural processes.

Figure 6–10
Chart showing Hypotheses and Alternative Hypotheses for Mass and Size-grade analysis.

Hypothesis
If the distribution of lithic materials from the pre-Clovis assemblage has not been affected by post-depositional site formation processes, then I expect no horizontal or vertical sorting of items by size across a common surface.

Alternative Hypothesis
If the distribution of lithic materials from the pre-Clovis assemblage has been affected by post-depositional site formation processes, then I expect evidence of such disturbance as the horizontal sorting of items by size across a common surface, or the vertical sorting of artifacts by size.
ArcGIS 10.0, to create three dimensional visualizations of the imported data. A nearest neighbor
analysis was used to evaluate the spatial patterns of the lithic deposits at the site. The analysis is
conducted for lithic materials observed within the Topper Clovis, Pleistocene Sands, and
Pleistocene Terrace assemblages. This analysis operates under the assumption that non-random
patterns within the assemblage should exist if: 1) the distribution of lithic artifacts is a byproduct
of human manufacture, and 2) site integrity has been preserved. Although clustered or uniform
distributions can occur resulting from in situ weathering or as a consequence of displacement,
additional analyses including artifact size grade, inclination, and cluster shape morphology are
employed to distinguish these processes from the byproducts of human manufacture.

If the Topper assemblage was a byproduct of taphonomic disturbance or represents the
displacement of flakes from the Clovis contexts above, then I expect the spatial distribution of
the assemblage to consist of 1) a random pattern throughout the horizontal and vertical profile, 2)
a non-random pattern whereby artifacts are vertically clustered with regard to possible cracks in
the sediment, or 3) a non-random pattern whereby fluvial processes have removed or
redistributed a portion of the extant assemblage. By contrast, a non-random (clustered) pattern
for the Topper assemblage that 1) exhibits no evidence of fluvial displacement or 2) evidence of
in situ weathering is considered representative of human agency.

Although lithic clustering is often associated with human agency, post-depositional
processes can create distributions that appear cultural in origin. Natural disturbances such as tree
throws can affect the integrity of archaeological deposits, often displacing materials with respect
to the vertical profile of the deposit. Moreover, untested cobbles may be fractured through
mechanical weathering and may cause items to migrate up or down the vertical profile.
If the pre Clovis deposits at Topper have undergone little disturbance, then the spatial distribution of the assemblage should be distributed horizontally as opposed to vertically with regard to a common working surface, and should exhibit a non-random (clustered) pattern. A non-random distribution, whose lithic contents cross cut multiple stratigraphic horizons, is evidence of disturbance regardless of the technological nature of the lithic assemblage and implies upward or downward movement.

Sullivan and Rozen’s Interpretation free categories may also be employed to evaluate site integrity. If there is a nonrandom (clustered) pattern to the spatial distribution of artifacts that meet the minimum criterion of debris, and that such a pattern is oriented horizontally with regard to a common surface, then barring evidence of fluvial or mechanical weathering processes, the assemblage is considered the byproduct of human agency. By contrast, if the spatial distribution of artifacts that meet the minimum criterion of debris is random, or is distributed vertically with regard to the stratigraphic profile, then the assemblage is considered a product of bioturbation or downward drift of flakes from above.

An inter assemblage spatial analysis was conducted for the Clovis, pre Clovis Pleistocene Sand, and pre Clovis Pleistocene Terrace assemblages. If the Topper pre Clovis assemblage is a byproduct of taphonomic disturbance or represents the displacement of flakes from the Clovis contexts above, then the technological tool and debitage composition for each assemblage should either 1) be randomly distributed throughout the vertical profile, or 2) display evidence for a decrease in size with depth. If this is the case, then tool types consistent with Clovis lithic technologies should occur in deposits associated with the Topper pre Clovis assemblage and should exhibit little stratigraphic integrity. However, if the Topper pre Clovis assemblage is a byproduct of human agency, and has been unaltered by post depositional processes, then the
technological tool and debitage composition for each assemblage should be non-randomly
distributed throughout the vertical profile at the site, assuming each assemblage is in
stratigraphically discrete deposits. Artifact categories selected for this analysis include bifaces,
core tools, flake tools, and bend breaks.

In addition to the nearest neighbor analysis, a K-means cluster analysis was used to
identify spatial patterning among the assemblage and within individual tool classes from the
assemblage. K–means is a non-hierarchical clustering program that searches for clusters on input
data that reduce the squared distance between a cluster’s centroid and points in the cluster (SSE)
(Kintigh and Ammerman 1982). The optimal cluster number is subsequently determined based
on the plot of Within Sum of Squares (SSE) by the number of clusters. The program assumes that
the variance of the horizontal distribution of each attribute is roughly spherical, and that each
cluster has approximately the same number of observations. The presence of clustering by
artifact type could indicate the presence and location of individual activity areas at Topper.

Refit Analysis

For this study, all three-dimensionally mapped items were evaluated for their potential to
refit. Where two or more lithic items are found to refit, their orientation (strike and dip) and
spatial location in relation to the site grid were noted, and used to inform about site integrity.
Artifacts were examined to assess refit potentiality as encountered during the attribute analysis.
Possible detachment scars on lithic items were examined, typically from one to three minutes per
specimen. Items that exhibit scar patterns that could refit were subsequently compared.
If refits were found among the assemblage, then I assume that their orientation and stratigraphic
position within the vertical profile is either the result of human agency, or is the byproduct of
natural processes. Bioturbation processes may act to displace artifacts along the vertical profile

233
of an archaeological deposit, whereas water, erosion, and colluvial processes may also act to redistribute deposits horizontally. Refits that have undergone little or no natural disturbances should cluster. As such, the distribution of refits, if produced by humans, and barring displacement, should be non-randomly distributed.

While the above methods deal with the presence and spatial array of refits within the Topper assemblage, additional analyses are needed to assess the agent of fracture that produced each refit. Since natural processes not only can redistribute artifacts of cultural origin, but can also create fracture patterns that appear to have been produced by humans, there is a need to distinguish refits as a product of natural versus cultural origin. Therefore, if two or more lithic detachments that meet the minimum definition of human agency refit, and both items are found on a common surface, and in relative proximity, then the resulting association is considered evidence of chipped stone tool production. By contrast, if two or more detachments refit, but do not meet the minimum definition of human agency, then the resulting association is considered the product of natural processes. Furthermore, if there is no relationship between the spatial array of refits, then the items have likely been displaced by posdepositional processes. The refit study is designed to serve as a proxy for understanding and distinguishing between site formation processes and those that could result from lithic production. Because the refit study is not comprehensive, the results should not be used to interpret the intensity of on-site lithic production.

_Cortical Analysis_

The presence of cortex and cortical pebbles at a site is an indication of either human lithic reduction episodes, or geological processes that have acted to degrade lithic materials over time.
Cortical analysis is employed as a means to identify the presence and intensity of lithic reduction episodes at Topper, and to determine the extent of post depositional weathering of chert cobbles. In chipped stone tool production, if reduction begins with the removal of flakes from a natural unmodified cobble, it should produce debitage that takes the form of cortical flakes, cortical debris, or cortical pebbles. Cortical debitage detached by human lithic manufacture typically exhibits evidence of lines of applied force (compression rings) on the interior face of the flake. However, cortex can also become detached from a lithic cobble through bipolar production or through the natural weathering of the exterior surface of the specimen. The percentage of these weathering detachments can then be compared to the percentage of flakes within a level to determine if the assemblage was more likely formed by cultural or natural processes. The on-site presence of cortex and or cortical debris is an indication of either 1) human lithic reduction episodes, or 2) natural geological and physical processes that have acted to weather or degrade lithic materials over time.

For this analysis, I compare each 5cm level of excavated material with regard to the size, amount, and weight of cortical debris and cortical pebbles from each unit. Areas at Topper where there are high concentrations of cortical debris or pebbles in association with chipped stone tools and flakes that meet the minimum definition of human agency are considered evidence of culturally produced deposits. The weight of cortical debris, cortical pebbles, quartz pebbles, and lithic flakes obtained from the sediment matrix in each unit was examined for each 5cm level from the top of the Clovis deposits to the base of the Pleistocene Terrace. The data allow for both horizontal and vertical comparison of the assemblage over the sample of units examined for the study. If the percentage of cortical pebbles is high when observed in stratigraphic association with artifacts that meet the minimum definition debris, than this association is likely the result of
lithic production. However, the presence of such items in a random distribution and that is not sorted by size, and which shows no correlation with identified artifacts, is not considered a byproduct of lithic production, and may instead be a product of natural processes. It is important note that that any distribution of cortical pebbles also be considered relative to the distribution of items that meet the minimum definition of human agency (debris) when making interpretations regarding the source of origin of the cortical assemblage.

Like cortex, quartz pebbles can also be deposited on a site as a result of postdepositional processes. At Topper, quartz pebbles are an indication of input by fluvial processes such as the Savannah River or Little Sweetwater Creek. The percentage and spatial distribution of quartz pebbles in a level can be compared with the percentage of flakes and cortex to determine the agencies most responsible for deposition at the site. High densities of flakes found in association with rounded quartz pebbles presents a greater likelihood that the existing flakes were transported to the location of discovery by fluvial activity, or that the flakes were created as a result of bombardment during fluvial processes.

*River Stained Cortex Analysis*

The presence of river staining on the exterior cortex of each mapped piece, as well as the weight of river stained cortex from the screen bags was examined. An examination of the distribution of river–stained cortex across the site may inform on patterns of lithic quarry behavior through time. If there is no change in the distribution of river–stained cortex throughout the vertical depth of the excavation profile, then I assume that there was little change in quarrying behavior at Topper through time. However, if there is evidence for river staining on Clovis artifacts, then the absence of river–stained artifacts that meet the minimum definition of human agency from the underlying deposits is 1) evidence for a pre Clovis occupation at the site.
or 2) simply indication of extensive weathering, due to the prolonged time the materials have been in the ground. In the latter scenario, it also follows that all materials within the weathered pre Clovis deposit, barring displacement from above should also be extensively weathered.

It should be of note that Allendale chert is susceptible to patination over time. Therefore, it is plausible that such patination has obscured evidence of river stained cortex. It is also possible that river–stained chert flakes from the Clovis deposits are simply migrating through the stratigraphic profile by displacement and are subsequently weathering in the older coarser Pleistocene Sands. To evaluate this possibility I compared the vertical distribution of river–stained chert from the Holocene, Clovis, Pleistocene Sands and Terrace deposits with the distribution of other conditional categories of chert. To account for the possibility that river stained cortex is simply being displaced from above I examined the quantity by weight of river stained cortical flakes per level. A gradual decrease in flakes through the profile is an indication that some flakes are being redeposited into the underlying strata. The possibility also exists that processes related to weathering have removed some or all evidence of river stained cortex on chert items. If weathering processes have altered the assemblage, then it follows that these same processes have also removed evidence for other conditional attributes on chert items from the deposit as well. One such attribute is thermal alteration. Therefore evidence of the extent of displacement and weathering should be indicated by the point in the stratigraphic profile where river–stained and thermally altered flakes are no longer visible. If both conditional attributes are absent from a given deposit, the likelihood is greater that such an absence resulted from weathering. By contrast, the occurrence of one attribute and absence of another from the profile suggests that the difference is less likely to have been the product of weathering, and more likely the result of cultural processes.
Mass and Size Grade Analysis

All lithic materials recovered from each provenience at Topper were examined by size. For this analysis, materials were passed through a series of nested screens to determine size grades: 1–inch, 1/2 inch, 1/4 inch, and 1/8 inch. Materials from each size grade were subsequently counted and weighed. Size grade analysis is employed to assess site integrity, specifically the horizontal and vertical displacement of artifacts by size. Research has shown that horizontal size sorting of artifacts is one potential indicator of post depositional processes such as fluvial or aeolian transport that could affect site integrity (Gunn and Foss 1997:53). Vertical size sorting of artifacts is a potential indicator of postdepositional processes such as bioturbation. Krotovina are natural agents that may displace smaller artifacts into deeper strata from stratigraphically higher intact deposits. To test whether post depositional agents have sorted artifacts by size across the site, all mapped and screened materials were examined by size:

If the distribution of lithic materials from the assemblage has been affected by post depositional site formation processes, then evidence of such disturbance would be: 1) the horizontal sorting of artifacts by size across a common surface, or 2) the vertical sorting of artifacts by size. In addition to measuring lithic materials by size, artifact density was examined by level. The total counts and weights of identified artifacts were recorded for each excavation level, divided by the volume of the bulk provenience. Compared against the vertical profile, greater quantities of artifacts in the form of debitage should exist in areas where lithic reduction and stone tool manufacture were the greatest.

Chapter Summary

Topper is one of the largest Clovis lithic workshop sites identified in the southeastern United States. If people were occupying Topper and exploiting this abundant lithic resource prior
to Clovis, then evidence for such exploitation should be present in the form of recognizable stone tools, or debitage resulting from the manufacture of these tools in deposits that pre date Clovis and show no evidence for disturbance. Chapters 7–11 offer the results of analysis. Chapter 7 presents the results of the lithic analysis with emphasis on the debitage and stone tool analyses. Chapter 8 offers the results of the experimental analysis while chapters 9–11 present the results of the distributional analyses.
CHAPTER VII
RESULTS OF LITHIC ANALYSIS

Interpretation Free Analysis

This study examined the lithic materials recovered from 16 2m x 2m units of Holocene and Pleistocene Sand sediments, and 12 1m x 1m units from the clay Pleistocene Terrace that underlie the Pleistocene Sands at the Topper Site (38AL23). An interpretation free analysis adapted from Sullivan and Rozen (1985) was conducted for the piece plotted items recovered from the study sample. The frequency of piece plotted and screen artifacts for each interpretation free category are presented in Table 7–1. Percentages of items per unit are presented in parentheses. A total of 4,286 lithic items were systematically examined for the interpretation free analysis. Of the lithic items examined, 195 were from the Clovis deposits, 786 from the Pleistocene Sands and 3,305 from the Pleistocene Terrace. Although there is a significant difference in the quantity of items examined from each stratigraphic deposit, I use proportions as well as raw counts when describing the characteristics of each assemblage. According to the Interpretation Free Analysis of all piece plotted lithic items from the sample units, the Topper assemblage consists of 193 complete flakes, 116 broken flakes, 344 flake fragments, 729 pieces of debris, 1,597 pieces of amorphous debris, and 1307 pebbles (Table 7–1). Appendix 29 gives the results of the Interpretation Free Analysis and illustrations of artifacts, while Appendices 30–33 present the metric, technological and conditional attributes for all mapped items from the study sample.

In addition to the mapped items, this study resulted in the identification of 70,074 pieces of lithic debitage (complete flakes, broken flakes, flake fragments, debris and amorphous debris) from the screen bags from these units. It should be noted that the screen materials were
Table 7–1
Results of Interpretation Free Analysis for frequency of mapped debitage types by stratigraphic unit. Number of items by type for each strata followed by percentage of items the category represents in parentheses.

categorized by debitage class and were further analyzed by condition, but did not undergo the full attribute analysis that was conducted for the artifacts piece plotted. As a consequence, the screen materials are not included here as part of the interpretation free analysis but are discussed in greater detail in chapters 8 and 9. In the following section I discuss the results of the interpretation free analysis for the Clovis, Pleistocene Sands, and Pleistocene Terrace deposits.

**Complete Flakes**

**Complete Flakes, Clovis**

A total of 27 complete flakes containing a distal terminus were identified from the piece plotted Clovis deposits from the study sample. Figures A29–1 and A29 – 2 present a sample of complete flakes identified from these levels. These flakes represent approximately 15% of all non–tool Clovis items that were mapped from the selected 16 2m x 2m units. Table 7–1 shows the distribution of debitage categories by stratigraphic unit. What is immediately obvious from this table is the higher quantity of plotted items from the Pleistocene Sands and Pleistocene Terrace. These totals could lead one to presume that higher rates of lithic reduction were carried out in these lower levels than in the overlying Clovis and Holocene deposits. However, it is important to note that these findings result from 1) a much greater volume of sediment that was excavated from the lower deposits at the site and 2) increased precision in the mapping protocol after 2005. For example, artifacts from only 58 5cm levels were examined from the Clovis deposits whereas 311 levels and 340 levels were examined from the Pleistocene Sands and Pleistocene Terrace deposits, respectively. Because of the extensive differences in the sample sizes from each stratigraphic unit, I provide the artifact percentage data in addition to frequency data for each assemblage.
When the overall percentage of artifacts is considered, Table 7–1 shows a decrease in the percentage of complete flakes in the Pleistocene Sands (5.59%) and Pleistocene Terrace (3.69%) compared to the Clovis deposits (13.8%). Table 7–1 also shows the mean number of piece plotted items per 5cm level (in meter²). On average, more complete flakes from the Clovis deposits were mapped per level than from the underlying strata.

Based on the proportion of complete flakes from the sample, it is evident that there are differences between the debitage categories for each stratigraphic unit. A Pearson’s Chi–Square test was conducted comparing the frequency of flake types (complete flakes, broken flakes, flake fragments) by strata. Table 7–2 presents the results of this test which demonstrate a significant difference between the populations ($\chi^2$ statistic; 4.6998, $p = 0.030166$). A subsequent Chi–Square test examined the frequency of flake categories for each assemblage and also resulted in a significant difference between the Clovis and underlying assemblages (Table 7–3). Although there are more complete flakes from the Pleistocene Sands and Terrace, the Clovis deposits have the highest percentage of complete flakes and a lower percentage of broken flakes and flake fragments. This finding demonstrates a higher proportion of flake breakage with depth through the stratigraphic profile at the site.

Table A33–1 presents the metric attributes of complete flakes for each stratum. A unique characteristic of the Topper Clovis flake assemblage is the significant variation observed in flake dimension indicating that there was no standard detachment size. Ratios of Length to width demonstrate this variability, although an examination shows a positive correlation in the ratio of complete flake length to width and also in flake width to thickness (Appendix 29, Figure A29–12– and A29–13). Table 7–4 presents the minimum, maximum, and mean attributes for complete

Min= minimum; Max=maximum; Av.=Average
flakes for each stratum. Although Clovis flakes are smaller than flakes from the Pleistocene Sands, they are considerably larger than flakes from the Pleistocene Terrace (Table 7–4).

The complete Clovis flake assemblage was subsequently examined by condition and attributes of the exterior and interior surfaces (Appendix 33, Tables A33–2 and A33–3). Clovis flakes typically have feather terminations, lack evidence of thermal alteration, and are a product of upland as opposed to river stained chert. An examination of flake exteriors show that most Clovis flakes are secondary or interior as opposed to cortical (Table A33–3). Given the complete cortical and secondary flake sizes, the largest flakes were detached from Clovis cores that were at least 70mm in length. A Pearson Chi–Square test comparing flake class by stratigraphic unit demonstrates a statistically significant difference between each assemblage (Table 7–5). The Clovis deposits have a higher percentage of tertiary flakes compared with flakes from the Pleistocene Sands or the Pleistocene Terrace. Clovis flakes are further characterized by either having unidirectional or multidirectional removal scars. Flakes that have unidirectional scars frequently exhibit attributes characteristic of blades, whereas flakes with multidirectional scars share attributes consistent with biface thinning flakes. An examination of the lateral margins shows that a higher percentage of Clovis flakes exhibit modification compared with the complete flakes from deeper deposits (Table 7–6). The range of retouch scars on Clovis flakes is lower than was found to occur on flakes from the Pleistocene Sands (Table 7–7, 7–11). In terms of size, modified flakes from the Clovis deposits tend to be longer than unmodified examples, implying a preference given for the selection of longer flakes for use (Table 7–7).

**Complete Flakes, Pleistocene Sands**

The interpretation free analysis resulted in the identification of 44 complete flakes from the Pleistocene Sands. Examples of the flakes from these deposits are illustrated in Figure A29–

</table>
4. There is a lower percentage of complete flakes from the Pleistocene Sands than from the overlying Clovis deposits (Table 7–1). These patterns could reflect a temporal change in reductive technology, or the displacement of artifacts into deeper strata as the result of bioturbation. When examined by size, flakes from the Pleistocene Sands tend to be longer, wider, and heavier than flakes recovered from Clovis contexts (Table A33–1), and also have a greater range in length (Table 7–4, Figure A29–29). These patterns are intriguing given the prospect for bioturbation or artifact displacement within the Pleistocene Sands. If artifact displacement by postdepositional or taphonomic processes were responsible for the distribution of artifacts through the vertical profile at the site, the expectation is that flakes should decrease in size with depth. However, based on the results, this is not the case. Whereas Clovis flakes are proportionately long compared to their width, complete flakes from the Pleistocene Sands tend to be proportionately thicker. Such morphological changes in flake form through the profile are more likely to reflect variation in raw material selectivity and reduction technique than they are the result of artifact displacement by disturbance.

Apart from morphology, a number of technological and condition attributes characterize the flake assemblage from the Pleistocene Sands (Tables A33–2 and A33–3). Thermal alteration was absent on mapped flakes from the stratum and the occurrence of river–stained cortex was rare. An examination of the complete flakes recovered from the Pleistocene Sands screen further supports these results with only 46 of 42,484 flakes identified that exhibit river stained cortex compared with 1,054 of 11,638 flakes identified from the Clovis screen bags (See chapter 9 Table 9–3).

Exterior surface attributes include removal scar patterns that are predominantly multidirectional with a mean scar frequency comparable to flakes from the Clovis deposits.
A unique aspect of this flake category is the absence of primary decortication flakes. An examination of the presence or absence of cortex on the exterior surfaces found that 65.9% (29 of 44) of flakes are secondary while the remaining examples are tertiary. Compared to the distribution of complete flakes from the Clovis deposits, a higher percentage of examples from the Pleistocene Sands were classified as secondary flakes, whereas a lower percentage of items were identified as tertiary (Table A33–3). Combined with the larger flake sizes, the apparent decrease in the proportion of tertiary flakes with depth could also imply lithic items from the Pleistocene Sands were not being reduced to final stages of the reductive trajectory or that final end products did not require the removal of all cortical material.

A lower percentage of modified flakes were recovered from the Pleistocene Sands compared to the Clovis deposits (Table 7–6). In all but a single example, lateral edge modification occurred on the exterior face of the flakes. These modified flakes are longer than unmodified examples and are also longer than modified flakes from the Clovis deposits (Table 7–7). These patterns may imply that lithic manufacture, if occurring prior to Clovis, was geared more toward the production of tools that could be used for cutting, slicing, and chopping, with less emphasis on biface and projectile point manufacture. A comparison of the proportion of modification on piece plotted items from the Clovis deposits to modified items from the Pleistocene sands shows that a higher proportion modified flakes and flake fragments occur from the Clovis deposits (Table 7–8). By contrast, the Pleistocene Sands have a higher proportion of modified debris and amorphous debris.

**Complete Flakes Pleistocene Terrace**

The interpretation Free Analysis resulted in the identification of 122 flakes from the mapped Pleistocene Terrace assemblage (Table 7–1). A much lower percentage of items were
identified as flakes from this deposit than from the overlying strata. Examples of complete flakes are illustrated in Figure A29–7. Flakes from the Pleistocene Terrace are on average the smallest and lightest flake category compared with similar artifacts from the overlying deposits (Table A33–1). The smaller artifact sizes for flakes and debitage from the Pleistocene Terrace could potentially reflect evidence of bioturbation, with the smaller items filtering through cracks in the sediment over time. If flakes had filtered through cracks in the sediment over time, the resulting spatial distribution and artifact dip and strike presented in chapter 11 should reveal evidence of such movement. It is also possible that the small sizes of flakes from the Pleistocene Terrace could reflect morphological variability in debitage patterns resulting from different load application techniques employed in the lithic reductive technologies of two different populations at the site.

Technological attributes that characterize the Pleistocene Terrace flake assemblage include exterior surfaces that are frequently cortical, scar patterns that are often unidirectional with higher percentages of cortex than flakes from other strata, and modification scars that when present, frequently occur on both interior and exterior surfaces of the flake (Table A33–2–A33 and A33–3). A comparison of the cortical attributes of the complete flakes shows that examples from the Pleistocene Terrace have a higher percentage of cortex than Clovis or Pleistocene Sands flakes, although secondary flakes are most common (Table A33–3). These secondary flakes typically exhibit fewer removal scars on the exterior surfaces (2.2%) than similar flakes recovered from the Pleistocene Sands (8.6%). Tertiary flakes represent the lowest proportion of flake types based on flake class. An examination of flake condition found an increase in the percentage of thermal alteration and an absence of river staining on flakes from the Pleistocene Terrace (Table A33–2). The absence of river staining implies that such cobbles
would not have been exposed and readily available for exploitation if peoples were present at the
time these materials were deposited.

Post detachment modification was identified on 16 complete flakes from the Pleistocene Terrace (Table 7–5), reflecting a lower proportion of the flake assemblage compared with similar items from the overlying strata (Table 7–6). Moreover, retouch scars on these flakes are comparatively infrequent (Table 7–7). Retouch scars on flakes from the Pleistocene Terrace, when present, tend to be intermittent, irregular, and randomly distributed along the flake margin; attributes that are more likely to have been the result of natural processes. Morphologically, modified flakes are short, compared with flakes from the Pleistocene Sands (Table 7–7) and are considerably lighter and thinner (Table A33–1).

**Broken Flakes**

**Broken Flakes, Clovis**

A total of twenty one broken flakes were identified from the piece-plotted Clovis deposits at Topper (Table 7–1). By definition, broken flakes exhibit a striking platform but do not have intact margins. Broken flakes identified are proximal fragments as opposed to medial or distal sections. Examples of Clovis broken flakes are presented in Figure A29–3. Technological attributes that characterize these flakes include terminations that end in hinges or steps, and exterior surfaces that lack cortex and that have multidirectional removal scars (Table A33–4 and A33–6). When broken flakes were compared by cortical class, the results of a Chi–Square test found no statistical difference in the distribution of broken flakes by assemblage at the .05 level (Table 7–9). At Topper, a number of bifacially worked broken items (n=9) were assigned to the Clovis broken flake category, and consist of portions that were broken and discarded during middle to late stages of the manufacture process. When examined by condition few broken flakes
were found to be thermally altered (5 of 21) (Table 7–1, Table A33–4). River staining was present, but was only identified on three broken Clovis flakes (Table A33–4). When all broken Clovis flakes were examined for the presence of modification, two examples were identified. These flakes each had more than 15 unidirectional removal scars from both margins of the flake.

In addition to the piece plotted broken flakes, a total of 1,842 broken flakes were identified from the Clovis screen bags (Table 7–1). This number reflects 15.82% of all debitage recovered from the screen bags from this stratigraphic unit. Apart from the amorphous debris category, fewer broken flakes were identified from the Clovis screen bags than from any other debitage category.

**Broken Flakes, Pleistocene Sands**

Twenty eight (28) broken flakes were identified from the piece plotted Pleistocene Sands assemblage (Table 7.1). Examples of these flakes are presented in Figure A29–5. As shown in Table 7–1 the proportion of broken flakes decreases through the stratigraphic profile at Topper. Attributes that characterize broken flakes from the Pleistocene Sands include termination types that end in steps fractures, exterior surfaces that exhibit prior detachment scars, and scar patterns that are multidirectional, indicating that such flakes were detached from multiple locations of the objective piece (Tables A33–4 to A33–6). The occurrence of cortex is rare on broken flakes from the Pleistocene Sands assemblage at Topper. Only a single cortical example was identified based on the attribute analysis. A higher proportion of broken flakes from the Pleistocene Sands are secondary compared with similar items from the Clovis deposits (Table A33–6). Removal scars on broken flakes range from 0 to 26 with a mean of seven scars per item. When examined by condition, all broken flakes lack river–stained cortex, and the occurrence of thermal damage is infrequent (Table A33–4). Broken flakes from the Pleistocene Sands displayed a comparatively
high incidence of modification. Compared with the Clovis samples (Table 7–5), retouch was observed on 14 (7.32%) of the broken flakes. Unlike Clovis broken flakes, examples from the Pleistocene Sands nearly always have retouch scars that occur on the exterior face of the specimen. Retouch scars on broken flakes from the Pleistocene Sands are comparatively fewer in number compared to similar artifacts from the Clovis deposits (Table 7–11).

**Broken Flakes, Pleistocene Terrace**

The Pleistocene Terrace broken flake assemblage consists of 67 piece-plotted proximal fragments and 647 broken flakes from the screen bags (Table 7–1). The piece plotted assemblage represents 2.02% of all mapped lithic categories recovered from the Pleistocene Terrace contexts. Examples of broken flakes are presented in Figure A29–9. By definition these flakes exhibit compression rings and a bulb of force on the interior surface of the flake. Most broken flakes are small, thick relative to their length, and end in step terminations. However, approximately 30% of the broken flakes end in feathered or hinged terminations.

The Pleistocene Terrace broken flake assemblage differs with respect to a number of technological attributes compared to broken flakes from the overlying deposits. A comparison of removal scar directionality shows that Terrace broken flakes are predominantly unidirectional, although multidirectional forms also occur with less frequency. By contrast, similar items from the Clovis and Pleistocene Sands have multidirectional scars (Table A33–4). When the number of exterior surface removal scars was tabulated, exterior scar counts were found to be much lower on broken flakes from the Pleistocene Terrace than on broken flakes identified from Clovis or Pleistocene Sands contexts (Table A33–4). The low frequency of removal scars on these broken specimens implies that they fractured as a result of natural processes rather than human agency. The exterior surfaces of broken flakes were examined by cortex. Unlike broken flakes
from the Clovis and Pleistocene Sands, most examples from the Pleistocene Terrace are secondary, with decortication flakes occurring infrequently (Table A33–6). Although cortical flakes are infrequent, the percentage of such flakes was found to increase in the Pleistocene Terrace compared with the distribution of broken flakes from the Clovis and Pleistocene Sands (Table A33–6).

River staining was not observed on any broken flakes from the Pleistocene Terrace. However, there was an increase in the percentage of thermally altered or thermally damaged broken flakes was compared to broken flakes identified from the overlying assemblages (Table A33–4). Table 7–6 presents the distribution of modified broken flakes. Although a higher frequency of modified examples were identified from the Pleistocene Terrace, a greater proportion of broken flakes were recovered from the Clovis deposits. Modification consists of 2–7 retouch scars removed from the exterior surface of the flake margin with a mean of 3.5 retouch scars per broken flake. Accordingly, modified broken flakes from the Pleistocene Terrace have fewer retouch scars per item than broken flakes from the Clovis or Pleistocene Sands. Given the incidence of modification combined with scar directionality observed on items from the broken flake assemblage, examples from the Pleistocene Terrace share more characteristics with breakage resulting from natural processes as opposed to lithic reduction.

*Flake Fragments*

**Flake Fragments, Clovis**

A total of 77 flake fragments were identified from the Clovis deposits (Table 7–1). Flake fragments have compression rings or a bulb, yet lack an observable point of applied force and intact margins. A number of attributes characterize the Clovis flake fragment assemblage. Clovis flake fragments are rarely cortical with most items consisting of secondary or tertiary removals
A Chi–Square test indicates a significant difference between the cortical, secondary, and tertiary flake fragments for each of the three assemblages (Table 7–10). Based on this table, more than the expected quantity of tertiary flake fragments were identified from Clovis deposits whereas less than the expected sum were found to be cortical or secondary. Scar patterns on Clovis flake fragments are more often multidirectional with a higher scar frequency than found on either the Pleistocene Sands or Pleistocene Terrace assemblage (Table A33–7). Thermal alteration and river staining were observed on Clovis flake fragments (Table A33–7). The thermal damage is more ubiquitous on Clovis flake fragments than on either the complete or broken flake artifact classes (Tables A32–2, A32–4, A32–7). While thermal crazing was not observed on complete or broken flakes from the Clovis deposits, such conditions were identified on flake fragments (Tables A32–2, A32–4, A32–7).

All flake fragments were examined for modification. Modification was identified on a higher proportion of Clovis items than similar artifacts from the underlying deposits (Table 7–6). Moreover, flake fragments also makeup the highest proportion of modified artifacts from any interpretation free category from the Clovis deposits (Table 7–6). Modified fragments typically have retouch flakes removed from the exterior face of the flake margin as opposed to the interior surface. Although retouch scars on modified flake fragments range in number from one to 12, such items have a lower mean retouch scar count compared to flake fragments from the Pleistocene Sands (Table 7–11). Most modified flake fragments were identified as shattered utilized flakes.

**Flake Fragments, Pleistocene Sands**

A total of 103 flake fragments were identified as piece plots from the Pleistocene Sands at Topper. Examples of these artifacts are illustrated in Figure A29–6. These flake fragments are
predominantly short, wide, and light. Technologically, examples from the Topper Pleistocene Sands are rarely cortical, and predominantly have prior detachment scar patterns that are multidirectional, with scar frequencies that often exceed 8 (Table A33–7). Most fragments are broken secondary detachments. The relative high proportion of secondary flakes from the deposit implies a general low emphasis placed on reducing objective pieces to stages of complete decortication. Compared with flake fragments from the Clovis deposits, examples from the Pleistocene Sands exhibit significantly fewer removal scars on the fragment exterior surface (Table A33–7). Distal terminations, when present (n=99 of 103) most often have feather terminations, with step and hinge terminations occurring with less frequency (Table A33–7). The relative scarcity of hinge terminations on fragments compared with the abundance of step terminations may be a product of flaws or vugs encountered in the raw material during the reduction process. All flake fragments from the Pleistocene Sands were examined by type. An examination of Appendix 32 shows that most flake fragments from the Pleistocene Sands are either indeterminate (46.6%) in form, or are medial (30%) sections. Only 25.24% of the broken flakes were identified as distal fragments and much fewer (1.94%) were classified as proximal. The high proportion of indeterminate sections relative to flake proximals implies high rates of shatter or breakage incurred during lithic reduction as well as little evidence for platform preparation and biface production.

When examined by condition, a low percentage of plotted flake fragments from the Pleistocene Sands were found to display evidence of thermal alteration. A total of 6 fragments (5.8%) exhibit thermal alteration, fewer than were recovered from either the Clovis (n=12, 15.6%) or Pleistocene Terrace (n=15, 9.14%) deposits. River staining is also rare, present on only one fragment (Table A33–7). When examined in greater detail, four of the thermally altered
flake fragments also exhibit modification along the lateral flake margins, and the lone river–
stained fragment is bifacially modified.

Tables 7–6 and 7–11 present the distribution of modified artifacts. There is an overall
decrease in the proportion of modified flake fragments from the Pleistocene Sands as compared
to similar items observed from the Clovis deposits. However, modified fragments from the
Pleistocene Sands have higher mean scar counts than modified fragments from the Clovis or
Pleistocene Terrace (Table 7–11). These modified flake fragments are longer than unmodified
examples and also exhibit higher numbers of prior detachment scars (9.7 to 6.3).

**Flake Fragments, Pleistocene Terrace**

A total of 143 piece-plotted flake fragments and 3,254 flake fragments from the screen
bags were identified from the Pleistocene Terrace assemblage (Table 7–1). A sample of these
items is illustrated in Figure A29–9. The flake fragments from the Pleistocene Terrace include 18
proximal sections, 6 distal sections, and 30 medial segments. A total of 45 fragments could not
be reliably identified with regard to condition. Attributes that characterize flake fragments from
the Pleistocene Terrace include exterior surfaces that are cortical, secondary or interior, with scar
patterns that are multidirectional with comparatively few (e.g. <4) removal scars, and distal
terminations that are feathered or end in steps (Table A33–7). Compared with flake fragments
from the Clovis and Pleistocene Sands, a slightly higher proportion of fragments from the
Terrace are cortical (Table A33–8). Secondary detachments make up the largest proportion of
flake fragments from the stratum. An evaluation of exterior surface scars shows that flake
fragments from the Pleistocene Terrace have lower mean scar counts compared with items from
the overlying deposits. Additional attributes characteristic of flake fragments from the
Pleistocene Terrace include an absence of river staining on flake surfaces yet a higher
percentage of thermally altered/damaged flakes compared with fragments from the overlying deposits.

A total of 39 flake fragments from the Pleistocene Terrace assemblage were found to have modification. The Pleistocene Terrace has the lowest proportion of retouched flake fragments (Table 7–11). Retouch includes uni-and bilateral retouch along one or both margins. Most flake fragments from the assemblage (70%) have modification on the exterior lateral margin of the flake while the remaining 30% are modified on both exterior and interior margins. Compared with the mean retouched scar counts on flake fragments from the Clovis and Pleistocene Sands assemblages, retouch scars on flake fragments from the Pleistocene Terrace are often fewer in number.

Debris

Debris, Clovis

Debris refers to all lithic items that have a discernible interior surface and compression rings, but lack a bulb of force, point of applied force and intact margins. Because debris lack many of the attributes consistent with conchoidal flaking, it is not always easy to distinguish the lithic technologies associated with flaking debris or if such materials are a byproduct of naturally fractured lithic items. A total of 17 debris fragments were identified from the Topper Clovis deposits. Clovis debris occur with less frequency than from deeper deposits (Table 7–1). All debris were examined and classified by metric and technological attributes. Morphological attributes for debris are presented in Table 7–12. A comparison of Clovis debris morphology shows that these items are frequently larger than complete Clovis flakes. Clovis debris are longer, thinner, and lighter than debris from the Pleistocene Sands. A correlation analysis found a strong positive relationship when Clovis debris length was regressed against measures of width
Table 7–12
Morphological Attributes of piece plotted debris size by stratum at the Topper Site (38AL23).

(.8621) (Figure A29–14). A positive relationship was also found when debris width was compared to measures of thickness ($r^2=.567$). If Clovis debris are the result of lithic manufacture, there is uniformity in flaking based on the correlation observed in the dimensions of these artifacts.

A number of technological attributes distinguish the Clovis debris category. Clovis debris are most often secondary or tertiary fragments that lack completely cortical exterior surfaces (Table A33–10). The near absence of cortical lithics from the Clovis contexts in this area of the site implies that cobbles were initially reduced to manageable forms elsewhere and then brought here for continued reduction and shaping. Technologically, flake debris exhibit removal scar patterns that are predominantly (86.96%) multidirectional as opposed to unidirectional (8.6%) or bidirectional (4.34%) (Table A33–9). Removal scars range from two to 27 in number, and have a higher mean scar count compared with debris from the deeper deposits at the site (Table A33–9). The high number of exterior surface removal scars found on these items indicates that Clovis debris were probably associated with the trimming and shaping of bifaces rather than the systematic detachment of blades from unidirectional cores at this location. However, the relatively high occurrence of step and hinge (56.51%) terminations on flaking debris are also evidence of high rates of errors incurred during the reduction process (Table A33–9). The lack of striking platforms and bulbs of force on these items are an indication that flake detachments shattered when force was applied to the objective piece. Modification was identified on 12 pieces of Clovis lithic debris, occurring with a higher percentage than observed on debris from the Pleistocene Sands or from the Pleistocene Terrace (Table 7–11). However, when scar counts were examined, debris from the Clovis deposits were found to have fewer retouch scars than
similar artifacts from the Pleistocene Sands. When examined by condition river staining and thermal alteration are rare on Clovis debris (Table A33–9).

In addition to the piece plotted debris, a total of 2,305 pieces of lithic debris were identified from the Clovis screen bags accounting for approximately 20% of all debitage recovered from the stratigraphic unit (Table 7–1). Given this distribution, the Clovis deposits have a lower proportion of small debris compared with the deeper assemblages. These findings could indicate that Clovis tool manufacture was more formalized; that debris from the Pleistocene Sands and Terrace reflect informal tool production or byproducts of natural processes; or that a higher percentage of debris originally discarded in the Clovis deposits has filtered into the underlying strata.

**Debris Pleistocene Sands**

A total of 166 items were classified as debris from the Pleistocene Sands. Examples of these debris are presented in Figure A29–7. Most lithic debris items from Pleistocene contexts vary considerably in morphology, yet are typically large compared with Clovis lithics of the same category (Table 7–12). Whereas Clovis debris may be described as relatively small, yet elongated in morphology, debris from the Pleistocene Sands tends to be blocky and irregular (Table 7–12). A total of 31 items categorized as lithic debris from the Pleistocene Sands (reflecting 18.67% of mapped items from the deposit) are heavier than 500g compared with only 1 (5.8%) item from the Clovis deposits.

A correlation analysis of debris morphology shows a positive association in the length to width ratios for Clovis and Pleistocene Sands debris ($R^2 = 0.8621$ and $R^2 = 0.8448$ respectively). When the debitage length to weight ratios were compared, debris from Clovis contexts are strongly correlated ($R^2 = 0.763$) while items from the Pleistocene Sands show no association ($R^2$
= 0.0002) (Appendix 29). The variation evident in debris size between these two stratigraphic units could reflect differences in technological strategies of lithic manufacture. For example, the large, blocky nature of the Pleistocene Sands debris assemblage could be linked to bipolar load application in the production of compression flakes. By contrast, debris from the Clovis assemblage is relatively uniform in morphology, and shares more attributes consistent with biface manufacture. It is also possible that the irregular nature of the Pleistocene Sands assemblage could reflect natural processes.

Debris from the Pleistocene Sands may be characterized as secondary or tertiary detachments, with exterior surfaces having multidirectional as opposed to unidirectional removal scars, and scar counts similar in frequency to Clovis debris (Table A33–9). An examination of the debris category by portion confirmed that in most cases (133 or 80%) the lithic items could not be assigned to a specific class and were subsequently labeled indeterminate. Of the debris that could be accurately identified, most items were classified as proximal sections, as opposed to medial or distal segments. An analysis of the termination types observed on Pleistocene Sands debris resulted in similar findings compared with items from the overlying Clovis deposits; most debris are either indeterminate or terminate in step fractures (Table A33–9).

A total of 73 pieces of mapped debris from the Pleistocene Sands exhibit modification. Although more of these artifacts exhibit modification compared to the frequency of Clovis debris, a comparison of the proportion of modified artifacts shows that a much larger percentage of the Clovis assemblage were modified (Table 7–11). Most modified debris from the Pleistocene Sands consist of the broken margins of retouched flake fragments. In the majority of cases, modification occurs on the exterior surface of the flake margin. Modification of both interior and exterior margins occurs with less frequency. Retouch scars on these items are similar
in average frequency with modified Clovis debris (Table 7–11). When examined by condition, debris from the Pleistocene Sands exhibit a greater range of thermal alteration than items from the Clovis deposits (Table A33–9.) Four of the thermally altered debris weigh in excess of 500g. These items could have fractured as a result of natural wildfires or possibly lightning strikes. However, Goodyear has proposed that fire was used by prehistoric peoples to break apart exceptionally large nodules that cannot otherwise be broken for subsequent lithic reduction (Goodyear personal communication). Of the thermally altered debris items identified from the depositional unit, all but three items display evidence of cultural modification.

In addition to the piece plotted debris, a total of 11,261 items were classified as debris from the Pleistocene Sands screen bags. A comparison with the Clovis assemblage shows that a higher percentage of artifacts from the Pleistocene Sands were classified as debris (Table 7–1). The differential frequency of debris between the two stratigraphic units could result from the use of alternative lithic reductive technologies between the two assemblages at the site, or the occurrence of naturally occurring chert in the deposits, given the possibility that some may have rolled down the hill. The flake formation, stone tool, and spatial analyses will examine these propositions in greater detail.

Debris, Pleistocene Terrace

There are 543 plotted items classified as debris from the Pleistocene Terrace. These include 21 proximal fragments, 25 medial segments, 61 distal fragments, and 435 items that were too fragmented to identify. A sample of debris items recovered from the Pleistocene Terrace is illustrated in Figure A29–10. Piece plotted debris make up a lower percentage of the sum of all lithic materials identified from the Pleistocene Terrace compared with the Pleistocene
Sands (Table 7–1). This implies that items with definitive compression rings are less common from the Pleistocene terrace than from the overlying deposits.

Figures A29–22, A29–23 and Table 7–12 show the distribution of debris by morphology for all piece plotted items from the Pleistocene Terrace. Similar to items from the Pleistocene Sands, debris from the Terrace vary considerably in morphology. In general, such debris items are smaller than similar items from the Pleistocene Sands. For example, much fewer debris items from the Pleistocene Terrace weigh greater than 500g (n =9) compared with the distribution of items from the Pleistocene Sands assemblage (n =31).

Debris from the Pleistocene Terrace most commonly consist of secondary detachments with multidirectional removal scars and with scar counts occurring in considerably lower numbers than found on debris from the Clovis or Pleistocene Sands (Table A33–9 and A33–10). Distal termination types are predominantly stepped (32.05%) or feathered (29.67%), with hinge terminations infrequent (0.2%). A total of 38.09% of all debris fragments were too fragmented to make a conclusive identification with regard to termination type.

A comparison of debris attributes from the Terrace with similar items from other strata result in a number of intriguing findings. Although secondary detachments occur with the greatest regularity, debris items from the Pleistocene Terrace have a higher percentage of cortical fragments than the overlying deposits (Table A33–10). Likewise, whereas multidirectional scar patterns occur most frequently from the stratum, a much greater proportion of debris from the Clovis and Pleistocene Sands have multidirectional scars. These patterns show that attributes consistent with reduction intensity decrease with depth across the site and imply that reduction was occurring with greater intensity in the Clovis and Pleistocene Sands. When examined by condition pre Clovis debris exhibit proportionately higher incidence of thermal alteration and
crazing than found on lithic debris recovered from more recent sediments. In total, 9% of all debris display evidence of thermal damage or thermal alteration. River staining was not observed on lithic debris from the Pleistocene Terrace.

Modification was identified on 173 piece plotted lithic debris from the Pleistocene Terrace (Table 7–11). Most modification includes chipping or retouch removed from the exterior lateral margin of the piece. Only on 4% of lithic debris was modification present on the interior lateral margin of the lithic item. A comparison of retouch scars on modified debris found that items from the Terrace have significantly fewer scars than modified items from the Clovis or Pleistocene Sands (Table 7–11). In most cases, debris exhibit one to two scars that are irregularly distributed along the margin of the lithic item as opposed to removal scars that are uniform in nature. Moreover, retouch on most debris was found on fewer than three segments of the debris margin, with a mean value of 2.55 segments of retouch per debris item. Compared with modified debris from the Pleistocene Sands, the Terrace examples are smaller in size, exhibit a lower average number of retouch scars, and have a lower percentage of retouched items in general (Table 7–11). If these modified items reflect chipped stone tools that have been broken or snapped resulting from use, then given their comparatively small size and distinct technological attributes, they were likely part of a separate reductive technology than items identified from the Clovis deposits.

Amorphous Debris

**Amorphous debris, Clovis**

Amorphous debris are lithic specimens that have a discernible interior surface, yet lack compression rings, a bulb of force, point of applied force and intact margins. A total of 30 piece-plotted items exhibit attributes characteristic of amorphous debris from the Clovis sample at Topper (Table 7–1). In addition to the mapped items, a total of 810 pieces of amorphous debris
were also identified from the screen bags. The frequency of amorphous debris is comparatively low for the Clovis deposits when considered relative to the frequency of amorphous debris from the deeper deposits at the site.

Like other flake categories from the Clovis deposits, most piece-plotted amorphous debris exhibit prior removal scars that are multidirectional in orientation (Table A33–11). However, amorphous debris were found to exhibit a greater percentage of detachments that have cortex or that are partially corticated compared with the other flake categories from the Clovis strata (Table A33–12). These findings suggest that amorphous debris were typically detached during earlier stages of the reduction continuum than flakes, broken flakes, and flake fragments. It is also possible that amorphous debris reflect errors incurred in the reduction process as flaws that were encountered in chert nodules. For example, all amorphous debris have pronounced stepping or crushing at the distal terminations of snapped specimens, an attribute that typically occurs when the energy from applied force does not travel evenly through the objective piece when struck. Such fractures occur when the objective piece is not struck properly, resulting in a failed or crushed detachment.

When examined by condition, thermal damage was an infrequent occurrence of Clovis amorphous debris, as well as on piece plotted amorphous debris from all strata examined. Only 6.6% (2 of 30) of all amorphous debris from the deposit exhibit thermal alteration (Table A33–11). Similarly, there is little evidence for river staining (2.77%) on amorphous debris from the Clovis deposits. Moreover, modification was infrequent with only a single example identified. The infrequent and irregular nature of possible removal scars from the lateral margin of this piece implies that such “modification” is not likely attributable to human agency.
Amorphous debris, Pleistocene Sands

There are 221 piece plotted items identified as amorphous debris from the Pleistocene Sands. These materials make up approximately 28% of all mapped items from the stratigraphic unit, and reflect an increase in the percentage of this artifact category compared with similar items identified from the Clovis deposits (15.3%) (Table 7–1). In addition to the piece plotted items, a total of 8,743 additional amorphous debris items were identified from the screen bags; significantly more than were recovered from the Clovis deposits. The morphological attributes of amorphous debris are presented in Table 7–13. Amorphous debris from the Pleistocene Sands are longer, wider and heavier than amorphous debris from the other deposits examined. Technologically, amorphous debris may be characterized as secondary fragments that retain partial cortex and are rarely completely cortical. Amorphous debris have multidirectional removal scars and have step-fracture terminations (Table A33–11). On average there are fewer removal scars on the exterior surface of amorphous debris from the Pleistocene Sands than there are on items from the Clovis deposits (Table A33–11).

Unlike other debitage types from the Pleistocene Sands, the percentage of modification on amorphous debris is infrequent, and is only present on 18 piece plotted items. However, a higher percentage of these artifacts were modified compared with the Clovis amorphous debris sample (Table 7–11). Most modified items consist of utilized chert cobbles and retouched quartz fragments. Retouch scars on modified specimens range from 2 to 7 in number with an average of 3.8 scars per item. When examined by condition, the presence of river staining was found to be absent on amorphous debris items from the Pleistocene Sands. Thermal alteration is rare, only occurring on four items (Table A33–11).

Amorphous debris, Pleistocene Terrace

There are 1,346 piece plotted lithic items identified as amorphous debris from the Pleistocene Terrace in addition to 6,142 examples recovered from the screen bags (Table 7–1). The piece plotted amorphous debris category makes up 40.72% of all lithic materials mapped from the Pleistocene Terrace; and represents the greatest frequency of any other lithic category from the deposits. Based on Table 7–1, amorphous debris items generally increase in number with depth at Topper. For example, compared with the overlying deposits, there is a greater percentage of amorphous debris from the Pleistocene Terrace than from the Clovis or Pleistocene Sands (Table 7–1). Morphologically, Pleistocene Terrace amorphous debris are smaller, thinner, and lighter than amorphous debris from other strata.

All Pleistocene Terrace amorphous debris items were examined for technological attributes of the exterior and interior surfaces. Most items are secondary detachments although primary (cortical) and tertiary detachments also occur (Table A33–12). There is an increase in the percentage of cortical amorphous debris compared with the frequency of items identified from the Clovis and Pleistocene Sands. Technologically, most amorphous debris consist of lithic items that exhibit prior removal scars that are multidirectional in orientation, terminate in step fractures, and lack evidence of river staining on the exterior surface. Removal scars on amorphous debris range from one to 11 in number, and occur in lower numbers than found on amorphous debris from the overlying deposits (Table A33–11).

Figure A29–11 illustrates a sample of the amorphous debris items that have been identified from the Pleistocene Terrace. Since amorphous debris lack a striking platform or bulb of force, the occurrence of these items from the Pleistocene Terrace could be the result of the natural breakage from weathering over time. The three lower items of Figure A29–11 lack a
striking platform and combined with the absence of compression rings or lines of force, imply that they are not likely to have been the result of lithic manufacture.

A total of 121 amorphous debris items from the Pleistocene Terrace are modified (Table 7–11). This frequency represents a higher percentage of modified artifacts compared with the distribution of modified amorphous debris from the Clovis or Pleistocene Sands levels. This finding is interesting given that the percentage of modification on other lithic categories decreases through the stratigraphic profile at Topper. However, most modified amorphous debris items from the Pleistocene Terrace have slightly fewer retouch scars per item (Table 7–11).

Patterned retouch is infrequent on these items and typically consists of two or fewer segments of the flake margin showing evidence of modification. By contrast, retouch on amorphous debris from the Pleistocene Sands is more uniform in nature and frequently consists of three or more parallel scars per working margin. When retouch location was considered, most modified amorphous debris (98.35%) exhibit chipping or retouch on the exterior margin of the lithic item whereas less than two percent of the examples have such chipping on the interior margin. The lack of consistently uniform retouch scars found on modified amorphous debris from the Pleistocene Terrace assemblage imply that these items were produced by natural as opposed to cultural formation processes.

*Pebbles*

*Pebbles, Clovis*

All lithic items that lack an interior or a discernible interior surface are classified as pebbles. As discussed in chapter 6, pebbles are defined as ranging in size from 4-64 mm, whereas cobbles range in size from 64-256 mm. However, for the purpose of this study, both morphological categories are subsumed under the label pebble as a simple method to distinguish their technological characteristics from other interpretation free categories.
Pebbles are typically byproducts of natural processes such as weathering and the deterioration of cherts over time. However, they can also occur as quartz pebbles that are suitable for use as hammer stones. The distribution of pebbles is presented in Table 7–1 and 7–11). Of the pebbles identified from the Clovis deposits, five items were made of quartz and two of these were subsequently identified as hammer stones. The remaining items are classified as natural cortical chert pebbles/cobbles.

The conditional and cortical attributes for the Clovis pebble interpretation free category are illustrated in Tables A33–13 and A33–14. Clovis pebbles lack many of the technological attributes consistently identified on other flake categories. For example, only a single item was found with identifiable removal scars on the exterior surface. Moreover, termination types were frequently indeterminate on pebbles, and those items that could be identified had step terminations. All Clovis chert pebbles were a product of upland chert and no examples were found to exhibit evidence of thermal damage. Likewise, modification was not observed on any item classified as a chert pebble from the Clovis deposits at Topper. Therefore it is assumed that these items are byproducts of natural formation processes and were not incorporated into the Topper toolkit.

One interesting aspect of the Clovis pebble category is the considerable variation in size of these materials. Although the largest pebbles were identified from the Pleistocene Sands and Terrace, Clovis pebbles are longer, and lighter than pebbles from other strata and are comparable in width with items identified from the Pleistocene Sands (Table 7–14). A positive correlation was found for the ratios of Clovis pebble length to width (Figure A29–24). The quartz pebbles and hammer stones were found to have a strong positive correlation in artifact weight to length.

and in the ratio of length to width. These findings suggest that people may have selected pebbles and cobbles for use as hammerstones based on morphological specifications.

**Pebbles, Pleistocene Sands**

A total of 224 piece plotted items were classified as pebbles from the Pleistocene Sands. Whereas pebbles comprise the smallest percentage of lithic debitage from the Clovis contexts (11.79%) they make up the largest proportion (28.4%) of lithic materials from the Pleistocene Sands. On average, pebbles from the Pleistocene Sands are comparable in morphology to the pebbles identified from the Clovis deposits although weights are frequently greater than Clovis counterparts. Pebbles from the Pleistocene Sands may be characterized as cortical (95.5%) and lacking in many of the identifiable attributes of lithic manufacture technologies (Table A33–13). For example, prior detachment scars on pebbles were only visible on 6 items or 2.6% of the population. Distal termination types were not identifiable on any specimen (Table A33–13). Additional attribute conditions that were not visible on Pleistocene pebbles include thermal alteration, river staining and intact margins.

Pebbles from the Pleistocene Sands display a low incidence of modification compared with other contemporaneous debitage categories (Table 7–11). Although eleven modified items were identified, this frequency reflects an increase in the proportion of pebble modification compared with the Clovis assemblage. Retouch scars on modified pebbles were variable, isolated, and not uniform indicating that they could have formed as a byproduct of natural formation processes rather than lithic reduction. Moreover, in all but three examples modification represented the only flake removals detached from a given pebble exterior surface. In summary, the modification attributes identified on pebbles from the Pleistocene Sands may be more indicative of postdepositional processes, than to byproducts of lithic reduction episodes.
**Pebbles, Pleistocene Terrace**

A total of 1,060 piece plotted lithic items were classified as pebbles from the Pleistocene Terrace. Apart from amorphous debris, the frequency of pebbles from the Pleistocene Terrace makes up the largest percentage of lithic items from any stratigraphic deposit at Topper. On average, Pleistocene Terrace pebbles are small in comparison to pebbles identified from the overlying deposits. There is an apparent decrease in the size of the piece plotted lithic pebbles through the stratigraphic profile at Topper (Table 7–14) When the Pleistocene Terrace pebble assemblage was examined by cortex, most (88.39%) items were found to be entirely cortical. A total of 106 (10%) pebbles were secondary or had a single detachment scar, while only six were classified as interior. Distal terminations, thermal alteration, and river staining were not identifiable on pebbles.

A total of 77 pebbles from Pleistocene Terrace contexts exhibit some form of modification. This number represents 23% of all modified items from the Pleistocene Terrace deposits. Pebbles display a lower incidence of modification compared with other contemporaneous debitage categories. Retouch scars on the modified Pleistocene Terrace assemblage were similar in form to items identified from the Pleistocene Sands; That is, they were isolated, irregular and non-uniform indicating that they could have formed as a byproduct of natural formation processes. Only eight pebbles were found to exhibit evidence of patterned retouch in the form of two or more consecutive removal scars along a single margin of the lithic item. In summary, modification attributes on pebbles from the Pleistocene Terrace are more indicative of lithic items that have been subjected to postdepositional processes than lithic reduction.

Interpretation Free Analysis Summary and Conclusions

The goals of the interpretation free analysis were to 1) determine if there are attributes containing criteria of human agency on lithic materials recovered from the Topper pre Clovis assemblage and 2) to determine if there is similarity in the assemblage composition and frequency of debitage categories for both Clovis and pre Clovis deposits. If peoples were exploiting the locally available chert quarry at Topper prior to Clovis, then I expect either similarity in assemblage composition and frequency of debitage categories for both Clovis and pre Clovis deposits, or the presence of debitage attributes containing indisputable criteria of human agency from the pre Clovis deposits. By contrast, if peoples were not present at Topper prior to the Clovis occupation at the site, then I expect a difference in assemblage composition and frequency of debitage categories for both Clovis and pre Clovis deposits and that the debitage attributes found on materials from pre Clovis deposits consist exclusively of amorphous debris or pebbles that could result from natural weathering processes.

The results of the interpretation free analysis demonstrate an unambiguous difference in the distribution of debitage categories when the Clovis and pre Clovis units are compared. The Chi-Square tests (Tables 7–3 and 7–15) validate this finding. The Clovis assemblage predominantly consists of complete flakes, broken flakes, and flake fragments and a higher proportion of these artifacts were assigned to the flake categories compared with lithic items from the Pleistocene Sands and Pleistocene Terrace deposits. Most complete Clovis flakes are the byproduct of biface manufacture given that the majority are biface thinning flakes. In contrast, the pre Clovis assemblages primarily consist of items classified as debris, amorphous debris, and pebbles. Therefore there is a difference in assemblage composition and frequency of
debitage categories when the Clovis and pre Clovis deposits at Topper are compared. The assemblages are not the same.

**Flake Formation Analysis**

Cotterell and Kamminga's (1987) model of flake formation was employed to determine the lithic reduction technologies selected for the manufacture of chipped stone tools at Topper. Technological strategies of lithic tool production considered for this analysis include: biface manufacture by conchoidal hertzian flaking; bipolar core reduction by compression flaking; and bend fracture flaking by either bending or compression forces. Flake types considered for this analysis included conchoidal flakes and bend break (fracture) flakes. Production materials include quartz hammerstones, quartz pebbles and anvil stones. In the section below, I provide a description and present the distribution of flake types identified for each stratigraphic profile at Topper. The analysis allows for a cross assemblage comparison of the distribution of each artifact form. While bend break flakes are discussed in detail in the section that follows, a thorough synopsis of bend break tools is reserved for the section on stone tool analysis.

The Topper piece-plotted assemblage examined consists of 568 conchoidal flakes and flake fragments, and 287 bend break flakes (Table 7–16). The frequency distribution of each flake type by stratum is presented in Appendix 34 and images of items from each flake class are presented in Figures A34–1 to A34–6. Both flakes and bend breaks increase in frequency with a corresponding increase in depth throughout the stratigraphic profile at Topper (Table 7–16). However, when only the percentage of these artifacts per stratum is considered, the percentage of conchoidal flakes decreases whereas an increase is evident for bend breaks. Neither flake class ever makes up more than 30% of the total lithic assemblage for each stratigraphic deposit. A Chi-Square test comparing the frequency of conchoidal and bend break flakes by stratigraphic...

Chi–Square statistic = 72.2475, p value is < 0.00001. The result is significant at p < 0.05.
deposit confirms that there is a significant difference between the two assemblages in terms of flake formation type (Chi–Square statistic =72.2475. P < 0.00001) (Table 7–17). Moreover, when the frequency of artifacts per 5cm level (1m x 1m) for each category was compared, the results still show a difference; bend breaks increase in abundance with depth relative to conchoidal flakes. In the sections below, conchoidal flakes and bend breaks from the Topper deposits are compared to determine if there is any difference in these artifact forms between each strata. Deposits included in this analysis are the Clovis, Pleistocene Sands and Pleistocene Terrace. Due to the extensive depth to which the Pleistocene Terrace was excavated, and because it represents two distinct subunits, the formation was subdivided into two subunits referred to here as the Upper and Lower Pleistocene Terrace.

Conchoidal Flakes

A total of 109 piece-plotted Clovis conchoidal flakes were identified from the study sample (Table 7–16). Although fewer conchoidal flakes were mapped from the Clovis deposits relative to deeper strata at the site, an examination of Table 7–16 shows that the number of mapped conchoidal flakes per level actually decreases with depth across the site. This pattern was not the same when the distribution of bend breaks was examined. The morphological attributes for the Clovis conchoidal flake category are presented in Table A34–2. A comparison of the attributes shows that Clovis flakes are shorter, thinner, and lighter than similar flakes from the Pleistocene Sands but are much larger than conchoidal flakes from the Pleistocene Terrace. Technological attributes of conchoidal flakes are presented in Table 7–18. Most Clovis conchoidal flakes are secondary or tertiary detachments have 10 or more removal scars that are predominantly multidirectional, with feathered distal terminations (Table 7–18).

</table>
When Clovis conchoidal flakes were examined by condition, most show no evidence of thermal alteration, although a comparison with the deeper deposits shows that a higher proportion of the Clovis assemblage is thermally altered (Table 7–18). River staining was also rare on Clovis conchoidal flakes. Further examination revealed a total of 22 modified conchoidal flakes from the Clovis assemblage. Given the relatively high number of scars on these flakes, it is likely that these flakes are the discard or waste products of onsite biface production although the occurrence of modification on some examples implies that flake tool production was also common.

Of the piece-plotted assemblage, a total of 155 conchoidal flakes were identified from the Pleistocene Sands (Table 7–16). On average, there are less than half as many conchoidal flakes from the Pleistocene Sands compared from the Clovis deposits. The morphological and technological attributes of all piece plotted conchoidal flakes from the Pleistocene Sands were compared to the attributes identified on conchoidal flakes from the Clovis deposits (Table A34–2, 7–18). Flakes from the Pleistocene Sands are on average longer, wider, thicker, and heavier than conchoidal flakes identified from the Clovis and Pleistocene Terrace deposits. The results of a Chi–Square test confirm that conchoidal flake morphology is statistically different between the Clovis and Pleistocene Sands (Chi–Square statistic= 21.9734. p value = .00006. (Table 7–2b). The difference in size between the two assemblages could be attributed to variation in manufacture technique, or to processes related to mechanical weathering.

Appendix 31, 32, and Table 7–18 present the conditional and technological attributes of piece plotted conchoidal flakes and bend breaks from the Pleistocene Sands at Topper. These flakes are characterized as secondary or interior detachments. The low percentage of cortical flakes from these deposits is intriguing. If natural processes were responsible for the production
of flakes, the expectation favors a high percentage of cortical flakes relative to interior or tertiary flakes. It is unlikely that natural processes will result in the removal of multiple flakes across the same location of an objective piece resulting in secondary or interior flakes. As such, the occurrence of high percentages of secondary and interior flakes from the Pleistocene Sands is more likely the result of either undisturbed human lithic manufacture episodes, or biotubated flakes. The results also show a higher percentage of multidirectional removal scars on conchoidal flakes from the Pleistocene Sands. However, scar counts on flakes from the Pleistocene Sands are lower in frequency than on Clovis examples (Table 7–18). The significantly higher scar count on Clovis flakes relative to items from the Pleistocene Sands might reflect the occurrence of intensive biface manufacture.

When examined by condition, most conchoidal flakes from the Pleistocene Sands were found to be complete, with broken and indeterminate flakes occurring with less frequency. Complete flakes end in feather terminations whereas broken fragments typically end in step fractures. Hinge terminations are infrequent. An interassemblage comparison shows a higher proportion of step fractures on flakes from the Pleistocene Sands than flakes from the Holocene and Clovis deposits. River staining is also absent on conchoidal flakes from the Pleistocene Sands. The lack of river staining on these flakes is interesting. Unless weathering has removed evidence of all river staining on these items, it is unlikely that their presence is the direct result of bioturbation. Unlike flakes from the Clovis deposits, a high proportion of conchoidal flakes from the Pleistocene Sands are modified. The high frequency of modified flakes combined with the rarity of bifaces from the Pleistocene Sands distinguishes the pre Clovis from Clovis deposits.

There are 304 conchoidal flakes from the Pleistocene Terrace. Table 7–16 gives the frequency of piece plotted conchoidal flakes from the Pleistocene Terrace as a proportion
relative to each 5cm level. Given the results, there is a decrease in the frequency of mapped conchoidal flakes per level through the Pleistocene Sands, with a subsequent increase observed for the Pleistocene Terrace. Because bioturbation and artifact displacement can lead to the accumulation of an abundance of small artifacts resting on a common surface, it was necessary to consider the morphological attributes of the conchoidal flake assemblage from the terrace. This was done to evaluate whether the observed increase in conchoidal flakes at the Pleistocene Sands/Terrace transition is a byproduct of natural processes. In essence, is the high proportion of observed flakes from the Pleistocene Terrace simply the result of the mass accumulation of numerous small flakes that have worked their way down through loose sandy deposits and into the top of the more resistant silty Pleistocene Terrace deposits, resulting in their resting on a common surface? To evaluate this proposition, I examined the morphological attributes of all piece plotted terrace flakes. Table A34–2 shows the results of the morphological analysis of conchoidal flakes from the Pleistocene Terrace. Flakes from the Terrace are smaller and lighter than examples from younger deposits in every morphological category. A One Way Analysis of Variance (ANOVA) test (Table A34–2) was conducted to determine if it is likely or not that the differences observed are due to random sampling. The results demonstrate a statistical difference for each assemblage by morphological measurements of length, width, thickness, and weight. Pleistocene Terrace conchoidal flakes are statistically smaller than flakes from the overlying assemblage.

Based on morphology, the possibility exists that conchoidal flakes from the Pleistocene Terrace could be the result of artifact displacement or bioturbation. However, it is also possible that these deposits reflect a stratigraphically intact assemblage of flakes and that the morphological differences evident in flake size could also be the byproduct of variations in the
reductive technologies of two separate assemblages. Therefore, it was necessary to consider the technological attributes of the Pleistocene Terrace conchoidal flake assemblage and to compare them to the flake assemblages from the Holocene and Pleistocene Sands.

Table 7–18 presents the technological and conditional attributes of conchoidal flakes from the Pleistocene Terrace. These flakes may be characterized as relatively small secondary detachments with three or fewer scars on the exterior surfaces that are typically unidirectional in form and have feather terminations. Although most examples are secondary, a higher proportion of conchoidal flakes from the Pleistocene terrace are cortical compared to the proportion of flakes from the Clovis or Pleistocene Sands. The higher percentage of cortical flakes and infrequent occurrence of multidirectional removal scars on flakes from the Pleistocene Terrace is interesting and could represent detachments by natural processes. Although most flakes from the Pleistocene Terrace have feather terminations, step fractures are also common. A Chi-Square test was conducted to determine whether there is a statistical difference in the frequency of flake termination types by stratigraphic unit. The results of this analysis (Table 7–19) show no significant difference in the frequency of termination types by assemblage for piece plotted conchoidal flakes at Topper (Chi-Square Statistic = 6.8766. p value = 0.142558.)

When examined by condition, the occurrence of thermal alteration is infrequent on flakes from the Pleistocene Terrace, occurring with slightly greater frequency than on flakes from the Pleistocene Sands. Modification was also found in a much lower percentage of flakes from the Pleistocene Terrace (Table 7–18). The results of a t-test comparing the number of retouch scars on flakes from the Pleistocene Sands and Pleistocene Terrace assemblage support the finding that there is a significant difference in the number of retouch scars on flakes from each assemblage (p<0.0001) (Table 7–20).

Because the Pleistocene Terrace excavation represents nearly two meters of lithic deposits, it was deemed appropriate to investigate the contents of this formation as two subunits: an upper Pleistocene Terrace that extends from 97.25–96.50m, and a lower Pleistocene Terrace that ranges from 96.50–95.25m (Figure 7–1). These two subunits correspond with unit designations 1b and 1a as defined by Waters (et al. 2009). Table 7–21 presents the distribution of mapped items from each Pleistocene Terrace subunit. Conchoidal flake morphology was compared for the upper (97.25–96.50m) and lower (96.50–95.25m) Terrace. Of the 304 conchoidal flakes identified, most were recovered from the upper Pleistocene Terrace. Table 7–21 also presents the mean size and removal scar attributes for modified and unmodified conchoidal flakes from each stratum.

A number of interesting patterns emerge from this analysis. First, there is no significant difference in flake size when unmodified flakes from the upper Pleistocene Terrace are compared with unmodified flakes from the lower Terrace. When the amount and distribution of exterior surface removal scars was compared it was found that flakes from the upper Pleistocene Terrace have a higher frequency of removal scars than flakes from the lower Pleistocene Terrace and the results of a t-test show that this difference is significant at the .05 level. Patterns were also evident in the morphology of the modified flakes identified from the Pleistocene Terrace. When conchoidal flakes were examined by modification, the modified flakes are significantly longer, wider, thicker and heavier than unmodified examples. Moreover, the modified flakes from the upper Pleistocene Terrace were, on average larger than modified flakes from the lower Pleistocene Terrace in every morphological category. Only when the attribute of flake width is considered is the difference between the two categories not statistically significant. Finally, an examination of retouch patterns on modified flakes from each stratum demonstrates that flakes
from the upper Pleistocene Terrace have twice as many retouch scars per working margin than flakes identified from the lower terrace. To summarize, conchoidal flakes from the upper Pleistocene Terrace exhibit attributes that are more consistent with cultural lithic manufacture (i.e., human agency) than flakes identified from the Lower Terrace.

*Bend Break Flakes*

Based on the results of the flake formation analysis, eight bend breaks were identified from the Clovis deposits. An example of a Clovis bend break is presented in Figure A34–4. Compared with the distribution of bend breaks from the Pleistocene Sands and Terrace, the occurrence of bend breaks is rare from the Clovis deposits at Topper (Table 7–17). Morphological attributes of Clovis bend breaks are presented in Table A34–3. Clovis bend breaks have two or more 90 degree break angles and are relatively short, thin and light. Clovis examples are shorter thinner and lighter than bend breaks from the underlying deposits. However, the results of a t-test comparing the mean difference in length between bend breaks from the Clovis and Pleistocene shows that the results are not significant at the p <0.05 level. (t-value = 0.658507; p = 0.513359) (TableA34–3).

Table 7–18 presents the technological attributes of Clovis Bend Breaks. Technological attributes consistently observed on Clovis bend breaks include exterior surfaces that have secondary detachments or that are tertiary, have multidirectional removal scars, and terminations that end in step fractures. When examined by cortex, most bend breaks from the Clovis levels are secondary or interior, with few cortical specimens identified.

By definition, bend breaks exhibit snapped terminations and broken lateral margins. Two of the Clovis bend breaks were modified, one of which exhibits modification on three distinct areas of the break margin. However, a detailed examination of the location of modification on
Clovis bend breaks found that retouch was always restricted to the artifact exterior surface as opposed to the interior surface. All bend breaks from the Clovis deposits were recovered near the base of the cultural horizon, and at the transition with the Pleistocene Sands deposits. Moreover, all but a single bend break from the Clovis deposits were recovered from the same 2m x 2m unit and within two contiguous 5cm levels. If bend breaks are the product of human agency these findings could imply that Clovis developed from the peoples who made the bend breaks. Based on the location of these artifacts from the base of the Clovis deposits, it is also plausible that these items were formed by trampling.

Bend breaks are commonly produced as a result of applying force on the acute edge of an objective piece. In Clovis assemblages, the sharp edge of a biface may snap or chip off and result in the formation of a bending flake when force is applied near the acute bifacial edge. The resulting bending flake will have a striking platform that is composed of a part of the original bifacial edge. Due to the thin nature of bend breaks from the Clovis sample, it is plausible that these artifacts represent snapped flakes that were broken unintentionally at some point subsequent to manufacture.

Artifacts typically associated with bipolar, bend fracture and compression flake technologies such as anvil stones, broken quartz pebbles, and chert pebbles are rare if not absent from the Clovis deposits at Topper (Appendix 34). Only ten broken quartz pebbles were identified from the Clovis sample and anvils were absent. Quartz pebbles may have been used as support platforms on which flakes may have been placed and intentionally snapped. The flake is placed across two pebbles and is subsequently struck at the midpoint of the flake. Such strategies result in bending fractures as opposed to compression fractures on the break margins of detached flakes. Attributes one might expect from this process include impact marks on the surfaces of
quartz pebbles. Alternatively, the flake may be placed atop a single quartz pebble and struck at its mid-point (compression flaking), thus using the pebble as an anvil. This process may result in the pebble splitting into two or more pieces. If so, fracture surfaces on broken pebbles should be flat and uniform as opposed to irregular in form. An examination of the broken quartz pebbles from the Clovis deposits at Topper found that most fractured surfaces are uneven as opposed to flat and are not consistent with having been used in the production of bend or compression fracture flakes.

The process of bend break or bipolar production has been found to often result in the detachment of numerous lithic byproducts. Chert pebbles are one hypothesized byproduct of bipolar production, though such items may also form as the result of natural weathering of lithic materials over time. Therefore, an analysis was conducted to compare the occurrence of bend breaks and chert pebbles from the Clovis deposits to determine if there is a correlation in the distribution of these artifacts across the stratigraphic unit. Very few chert pebbles occur in the Clovis deposits at Topper (n=23), and therefore, they were not likely byproducts of bend break manufacture in this cultural horizon. By contrast, a much greater percentage of pebbles, bend breaks, and potential bend break production items were recovered from the Pleistocene Sands. The results of a Chi–Square test comparing the proportion of artifacts associated with bend break manufacture per 5cm level by stratigraphic assemblage at Topper Site shows that the three assemblages are statistically different at the .05 level (Chi–Square statistic = 83.3309, p value = < 0.00001) (Table 7–22).

There are 45 piece plotted bend breaks from the Pleistocene Sands (Table 7–17). A sample of these bend breaks are illustrated in Figure A34–5. Four of the artifacts in this image exhibit uniform modification along their lateral, exterior margins suggesting that they are a

HS = Hammerstones
product of human agency. When the distribution of bend breaks at the site is considered, the percentage of bend breaks was found to increase with depth through the stratigraphic profile (Table 7–16). A higher percentage of bend breaks occur within the Pleistocene Sands than the Clovis deposits. However, the percentage of bend breaks from the Pleistocene Sands is relatively small (5.72%) compared to the cumulative total of mapped items from this stratigraphic unit (n=786). Based on the results of the morphological analysis, bend breaks from the Pleistocene Sands are longer, thicker, and heavier than examples identified from the Clovis levels (Table A34–3). On average, bend breaks from the Pleistocene sample were 26.3 mm in length compared to 23.1 mm for items recovered from the Clovis deposits. However, the results of a t-test comparing the difference in means shows that the results are not significant at the p <0.05 level. (t-value = .658507; P = .513359) (Table A34–3b).

Technological and conditional attributes for bend breaks from the Pleistocene Sands are presented in Table 7–18. Bend breaks from the Pleistocene Sands are predominantly made on secondary detachments, although interior specimens are also common, have four or more removal scars, two to three 90 degree break angles, and multidirectional removal scars on the exterior surfaces. The relatively high proportion of interior as opposed to cortical bend breaks is intriguing given that extended weathering processes would be required to completely decorticate these items. Bend breaks identified from the Pleistocene deposits were found to exhibit higher scar counts than similar artifacts identified from the Clovis deposits. Conversely, the results of a t-test comparing the number of bend break removal scars by assemblage found no statistical difference between the two assemblages (t–value = 1.038201; p value = 0.304074) (Table A34–3b). When all bend breaks were further examined by the cumulative number of detachment scars, examples from the Pleistocene Sands also have higher scar counts compared with Clovis
specimens (Table 7–18). On average, two to three of the detachment scars consist of 90 degree break angles, and are used to distinguish bend breaks from conchoidal flakes. Likewise, because bend breaks by definition exhibit snap fractures, they tend to nearly always terminate in step terminations. The results presented in Table 7–18 confirm this assertion and show that all but a single bend break from the deposits terminates in a step fracture. Removal scar directionality was examined to account for potential variability in reductive technology or to determine if natural processes were responsible for the production of bend break flakes. (I.e. a single unidirectional removal scar could result from natural processes). The results illustrated in Table 7–18 show that most bend breaks from the Pleistocene Sands exhibit multidirectional removal scars. Compared with the directionality patterns found on the distribution of artifacts from the Clovis deposits, the results are nearly identical for both assemblages, with 75% of the artifacts having scar patterns that are multidirectional.

When artifact condition was considered, thermal alteration was absent on bend breaks from the Pleistocene Sands. This same pattern was observed for the Clovis bend break assemblage. The higher percentage of thermal alteration on Clovis conchoidal flakes could indicate the potential that bioturbation has reworked a portion of the overlying assemblage into deeper deposits.

Table A34–11 shows the percentage of modified bend breaks identified for each stratigraphic deposit. Based on this table it is evident that a greater percentage of items from the Pleistocene Sands are modified compared with the frequency of modification found on bend breaks from the Clovis deposits. However, when the distribution is considered relative to the quantity of modified bend breaks per 5cm level, the variance between the Clovis and Pleistocene Sands assemblages is much less (Table A34–11). On bend breaks, modification typically consists
of two to four unidirectional uniform retouch scars taken from the exterior margin of the break surface. Retouch scars on these items range from 2 to 10 in number with a mean of 3.5 uniform scars per item. Only on one example is modification present on the interior surface of the artifact.

The morphological and technological attributes of modified and unmodified bend breaks from the Clovis, Pleistocene Sands and Pleistocene Terrace deposits are compared and the results presented in Table A34–12–14. Modified items from the Pleistocene Sands are frequently larger than those that are unmodified. Moreover, such bend breaks tend to have greater amounts of patterned exterior surface removal scars, a higher percentage of multidirectional removal scars, and a lower percentage of items classified as amorphous debris than bend breaks that lack modification. The results of multiple t–tests comparing the morphological and technological attributes of modified and unmodified bend breaks show that in most cases there is a significant difference in the two artifact populations for the Pleistocene Sands (Table A34–13). Consequently, evidence supports the premise that the modified bend breaks from the Pleistocene Sands are not the product of chance collisions with other lithic materials. Modified bend breaks from the Pleistocene Sands have higher number of break angles on average, although these differences are not statistically significant (Table A34–13). Such angles are thought to be well suited for cutting, slicing, or grooving purposes. When bend break modification was further examined by the location of potential retouch, it was found that systematic retouch occurred on anywhere from one to six segments of a given piece from the population. On average however, 3.2 segments of bend breaks from the Pleistocene Sands were found to exhibit some form of modification.

To help determine whether bend breaks were a product of natural versus human agency at Topper, the Pleistocene Sands assemblage was further examined by the frequency of other
artifact forms that might be associated with the production of bend breaks from the assemblage. The results were then compared with the contents of the Clovis assemblage as a test for similarity in assemblage composition. The number of broken quartz pebbles, anvil stones, and chert pebbles identified from the Pleistocene Sands is presented in Table A34–5–8. Based on these tables, there is a slight increase in the number and percentage of bend breaks, anvil stones, chert pebbles, and broken quartz pebbles with depth when the contents of the Clovis deposits are compared to the Pleistocene Sands. However, these differences are less substantial when the frequency of bend breaks is considered as a proportion of artifacts per 5 cm level. The most obvious difference between Holocene and Pleistocene Sands assemblages is the increase found in the distribution of chert pebbles. Chert pebbles comprise 24.26% of the Pleistocene lithic deposits, an increase of 18.38% compared with items recovered from the Clovis assemblage. The increase in the number of bend breaks in conjunction with a corollary increase in chert pebble debris might imply that these two categories are culturally related. However, an in depth examination of potential weathering processes is required to substantiate this claim, and will be discussed in the following chapters.

The morphological attributes of anvil stones and broken quartz pebbles are illustrated in A34–6 and A34–7. Anvil stones at Topper have scars on the upper surface of the boulder that result from hypothesized compression flaking. A total of nine artifacts that fit the description of anvil stones were identified from the Pleistocene deposits at Topper. Morphologically, these artifacts are large and range in size from 10g to 979.8g (Table A34–6). Exterior surfaces on anvil stones are either cortical or secondary. No anvil stones were found to be completely decorticated or tertiary. Anvil stones typically have multiple removal scars on the exterior surfaces, a possible result of compression flaking. Removal scars on the surfaces of anvils are frequently on the top
or bottom of the artifact and lack evidence of scars removed from the exterior margin. Such scars are attributed to bipolar reduction. Anvils lack any evidence of river staining or thermal alteration.

The distribution of broken quartz pebbles from the Pleistocene Sands deposits at Topper are presented in Table A34–7. These broken quartz pebbles are slightly heavier and larger than quartz pebbles identified from the Holocene contexts. An examination of the removal patterns on these pebbles also shows that they exhibit higher percentages of removal scars per item than quartz pebbles from the Clovis deposits (Table A34–7). The majority of fracture surfaces on quartz pebbles are flat and uniform as opposed to irregular in form, and are consistent with attributes associated with compression flaking. In addition to broken quartz pebbles, 22 quartz hammerstones were identified from the Pleistocene Sands. When examined by size, these hammerstones were on average larger than broken quartz pebbles from the same contexts. However, hammerstones recovered from the Pleistocene Sands tend to be smaller and exhibit fewer removal scars than hammerstones identified from the overlying Clovis deposits.

A total of 233 bend breaks were identified from the Pleistocene Terrace. This number represents 7.04% of all piece plotted items recovered from the stratum (Table 7–1, 7–18). The morphological and technological attributes of these items were compared to bend breaks recovered from the overlying deposits. Table 7–23 and Table A34–3 present the morphological attributes of bend breaks from the Pleistocene Terrace at Topper. Bend breaks from the Pleistocene Terrace are on average smaller and lighter than those identified from the Pleistocene Sands with lengths range from 6mm to 56mm (Table A34–3). However, the results of a One Way Analysis of Variance demonstrate that the observed differences are not statistically different at the 0.05 level (Table A34–3).

</table>
The technological and conditional attributes of bend breaks from the Pleistocene Terrace are presented in Table 7–18. These bend breaks may be characterized as produced on secondary detachments with three or fewer removal scars with removal scar patterns that are multidirectional. Compared with bend breaks from the overlying deposits, a higher proportion of those from the Pleistocene Terrace are entirely cortical. Likewise, when the proportion of tertiary bend breaks was examined by strata, a greater percentage of artifacts from the Pleistocene Sands were found to be tertiary compared with the Pleistocene Terrace assemblage (Table 7–18). These findings imply that bend breaks retain greater percentages of cortex as depth increases across the site. Bend breaks from the Pleistocene Sands also average nearly twice as many exterior removal scars than artifacts recovered from the Pleistocene Terrace, and have fewer examples with scar patterns that are multidirectional and non-uniform. The combination of non-patterned features, fewer removal scars, and greater percentage of cortex are attributes consistent with natural as opposed to cultural formation processes.

All Pleistocene Terrace bend breaks were examined by condition and for the presence or absence of post detachment modification (Table 7–18). Very few bend breaks were found to exhibit thermal alteration. River staining was also absent from all Pleistocene Terrace bend breaks. Of the bend breaks identified from the research sample, a higher proportion of examples from the Pleistocene Terrace were found to exhibit some form of modification (Table A34–11). Modification typically takes the form of 2 to 2.5 retouch scars removed from the lateral edge of the bend break margin. Interestingly, the percentage of modification on Pleistocene Terrace examples is slightly greater than the number of modified bend breaks identified from the Pleistocene Sands. However, a comparison of the morphological and technological attributes shows that there are a number of significant differences between these two samples (Tables
A34–3, A34–13, A34–14). First, modified Pleistocene Terrace bend breaks are smaller and lighter than those recovered from the overlying sands. Next, modified Pleistocene Terrace bend breaks average fewer 90 degree break angles than those identified from the overlying deposits. Such angles are considered useful margins for gouging and grooving organic media such as wood and bone, and artifacts with more 90 degree break angles would have served greater utility. When the scar patterns on bend breaks were examined, the modified Pleistocene Terrace bend breaks exhibit fewer retouch and exterior surface scars than similar artifacts classified as bend breaks from the Pleistocene Sands. Moreover, the retouch scars on Pleistocene Terrace items tend to be irregular in form compared with bend breaks recovered from the Pleistocene Sands. Retouch scars on bend breaks from the Pleistocene Sands are more uniform. Finally, a greater proportion of modified bend breaks from the Pleistocene Terrace were classified as amorphous debris, lacking compression rings or impact markers whereas modified items from the Pleistocene Sands were more frequently classified as debris. If bend breaks were produced by humans at Topper, then the morpho-technological attributes consistently found on examples from the Pleistocene Sands appear to have been better suited for use as tools compared with items recovered from the Pleistocene Terrace contexts.

There are also potential differences in the morphological and technological attributes of bend breaks from the Pleistocene Terrace when the sample was analyzed by the occurrence and extent of modification. To evaluate this possibility, an intra-assemblage analysis was undertaken to compare the attributes of modified and unmodified bend breaks from the Terrace (Table A34–14). The results of this analysis show that unmodified bend breaks tend to be smaller, have fewer break angles, and consist of a greater percentage of amorphous debris than modified bend breaks from the same contexts. Consequently, if bend breaks do in fact represent a culturally modified
assemblage at Topper then attributes such as material size and condition may have influenced which items were selected for use over others.

To better understand bend break technology at Topper, the lithic deposits from the Pleistocene Terrace were further examined as two separate subunits (Table 7–23). As for the conchoidal flake assemblage, the number and condition of terrace bend breaks was recorded for items recovered from two zones; 97.25–96.50m and 96.50–95.25m. At first glance, a number of intriguing patterns are evident. Foremost, a slight majority of bend breaks were recovered from the deeper subunit. In terms of morphology, items recovered from the deeper deposits of the Pleistocene Terrace also tend to be larger and heavier than bend breaks recovered from the overlying deposits. There appears to be a positive trend in lithic abundance and size with depth through the Pleistocene Terrace. This pattern is opposite the pattern one would expect if items are filtering through the stratigraphic profile through time. In addition to these attributes, more bend breaks from the deeper subunit are tertiary, have greater numbers of removal scars, and have a higher incidence of multidirectional removal scar patterns than items from the upper Pleistocene Terrace. A greater percentage of bend breaks from the deeper Pleistocene Terrace display evidence for modification. However, a closer inspection reveals that potential retouch scars on these items, when present, range in frequency from 2 to 2.5 scars per bend break,(less frequently than found on examples from the Pleistocene Sands), and are predominantly unevenly rather than uniformly distributed along the break margin. Such retouch could occur as the result of natural weathering processes or from lithic collision episodes. In fact, these patterns correspond satisfactorily with the proposition that the bend breaks from the lower Pleistocene Terrace are byproducts of natural processes such as sediment consolidation or natural breakage. However, other patterns are in agreement with a cultural origin for the terrace bend break
assemblage at Topper. The results in Table 7–23 show that modified bend breaks in both subunits are on average greater in size, have higher exterior surface scar counts, and exhibit a larger amount of 90 degree break angles than unmodified bend breaks. Accordingly, there does appear to be some relationship in the techno-morphological attributes of bend breaks and the incidence of modification within this stratigraphic unit. Based on these results, modified bend breaks at Topper consistently have a higher frequency of attributes indicative of human agency than bend breaks that lack modification.

*Flake Formation Analysis Summary*

The results of the flake formation analysis demonstrate that conchoidal flakes as well as bend break flakes occur in stratigraphic contexts that predate the Clovis deposits at Topper. The greatest percentage of conchoidal flakes are found in the Clovis deposits and reflect episodes of biface manufacture and core reduction. A corresponding decrease in the percentage of these flakes is evident with depth through the profile at the site. This pattern could reflect artifact displacement, or down-drift, as a result of bioturbation or even fluvial processes. However, based on the distribution of artifacts by size (Table A34–2) there is an apparent lack of size sorting of the piece plotted flakes when the Clovis, Pleistocene Sands, and Pleistocene Terrace assemblages are compared. While conchoidal flakes from the Pleistocene Terrace are smallest, the flakes from the Clovis deposits are smaller than those from the Pleistocene Sands. It should also be noted that although the mapping protocol called for a size threshold (> 2.5cm) in the recording of all lithic items encountered, artifacts smaller than the specified size limit were mapped if they were considered tools or byproducts of chipped stone tool manufacture.

The apparent lack of artifact size sorting at Topper is an indication that cultural processes could also be responsible for these patterns. Furthermore, the high incidence of modification
relative to unmodified flakes found to occur on flakes from the Pleistocene Sands (50.96%), and high patterned retouch scar counts (6) on conchoidal flakes from the Upper Pleistocene Terrace suggests that these artifacts are the product of human agency. The significant decrease in patterned retouch and retouch scar frequency found on conchoidal flakes from the mid to lower Pleistocene Terrace, combined with the smaller artifact sizes, and increased percentages of cortex for flakes recovered from these deposits suggests that these materials are more likely to have been influenced by post depositional processes such as bioturbation or in situ weathering than artifacts recovered from the overlying deposits.

In contrast to the flake assemblage, lithic artifacts that exhibit attributes consistent with bend break technologies are rare from the Clovis deposits at Topper, and increase in abundance with depth. The greatest percentage of bend breaks was identified from the Pleistocene Terrace. However, more square meters of excavation have been undertaken from this stratigraphic unit and modification on specimens from the deepest deposits of the lower Pleistocene Terrace are less uniform. Bend breaks from the Pleistocene Sands are larger and exhibit more attributes consistent with cultural modification than bend breaks from the Pleistocene Terrace. Moreover, artifacts associated with the production of bend breaks occur in the greatest quantities from the base of the Pleistocene Sands. The increased occurrence of anvil stones and cortical chert pebbles and the presence of split quartz pebbles with uniform margins together suggest the use of compression flaking in the manufacture of bend break flakes from the Pleistocene Sands. Modification retouch, when present on Pleistocene Terrace bend breaks, is more often inconsistent, and takes the form of fewer and intermittent retouch scars on the break margins. This pattern is most evident on items recovered from the lower Pleistocene Terrace deposits. As such, the prospect of human agency in the production of bend breaks from the lower Pleistocene
Terrace is less clear than it is for similar artifacts recovered from the Pleistocene Sands. The discovery of bend break and conchoidal flakes from the pre Clovis deposits at Topper warranted a subsequent analysis to determine if similar patterns are present in the distribution of stone tools through the stratigraphic profile at the site. The results of a stone tool analysis of the lithic materials identified from the Topper assemblage is presented in the following section.

**Stone Tool Analysis**

If people were making stone tools at Topper prior to Clovis, then it follows that there should be evidence for stone tools or stone tool production from the Pleistocene deposits at the site. Table 7–24 presents the counts and percentages of stone tools from the main strata using a morphological typology for chipped stone tools at Topper based on Andrefsky (2005:76). The typology is not intended to reflect the function of stone tools but is used to signify the morphology. The microwear analysis determined artifact function with greater precision. For this analysis, debitage was distinguished from stone tools when individual items were found to lack evidence of modification, or in the case of bend breaks, have two or fewer 90 degree break angles. Among the formal tools, six categories were defined that constitute 1,159 chipped stone tools. These include core tools (221), biface tools (75), flake tools (522), bend breaks (275), production tools (63), and choppers. The production tool class was not defined by Andrefsky (2005) but is defined here as any artifact that was used in the production of stone tools. The category is used in this study to help isolate and establish the lithic manufacture strategies that were incorporated in the production of chipped stone tools for each depositional unit. Examples of artifacts from each tool class by stratigraphic deposit are illustrated in Figures A35–1 to A35–53. The distribution of tools was compared for each stratigraphic deposit to evaluate the

frequency and types of tools recovered from the Clovis and pre Clovis assemblages at Topper. Similarity in toolkit composition would indicate that: 1) either two groups of peoples, separated in time, were using the same technological strategies of tool production and use; or 2) the tools observed from pre Clovis contexts were redeposited from Clovis deposits into deeper strata at the site. In contrast, dissimilarity in toolkit composition would indicate that two groups of peoples, separated in time, were using different technological strategies of tool production and use. The distribution of formalized chipped stone tools by type is presented in the section that follows.

Core Tools

Based on the morphological typology, a total of 221 core tools were identified at Topper (Tables 7–24, 7–25). Core tools were recovered from each of the three stratigraphic deposits examined (Clovis, Pleistocene Sands, and Pleistocene Terrace). Most core tools were recovered from the Pleistocene Sands with fewer cores identified from the Pleistocene Terrace, and Clovis deposits. The lowest percentage of core tools derives from the Clovis deposits (Table 7–25). Clovis cores consist of complete bifacial, blade, and flake unidirectional and multidirectional cores as well as core fragments (Appendix 35). Cores with unidirectional removal scars were rare from the Clovis deposits. Technological and morphological attributes of cores are presented in tables 7–26 and 7–27. Morphologically, Clovis core tools are smaller and weigh much less than cores that were identified from the deeper deposits; however, there is no significant difference in measurements of core length, width and thickness (Table 7–26). Clovis cores have fewer prior detachments scars than cores from deeper deposits (Table 7–26).

When Clovis cores were examined for the presence or absence of modification, six items were found to exhibit some form of modification. Clovis cores exhibit a lower incidence of

modification compared with cores identified from the Pleistocene Sands and Terrace (Table–7–25). An examination of the condition of the exterior cortical surfaces of Clovis cores found that most examples are made on upland chert. Only a single Clovis core exhibits river staining on its exterior surface. Core tools are the dominant tool class identified from the Pleistocene Sands. Figures A35–4 to A35–6 present examples of cores and core tools from the Pleistocene Sands at Topper. These cores are typically larger than Clovis cores. However, the results of a one way analysis of variance show no significant difference in the morphology of cores from the Pleistocene Sands with those from other deposits Table 7–26. Technologically, cores identified from the Pleistocene Sands are predominantly multidirectional, although three cores were identified as blade cores.

Core tools from the Pleistocene Sands have higher exterior scar counts, although the difference is not significant based on the results of a One Way Analysis of variance compared with cores from the Clovis or Pleistocene Terrace (Table 7–26). An examination for the presence or absence of modification found that 36% of cores from the Pleistocene Sands exhibit some form of modification, a higher percentage than observed on cores from the Clovis (12.5%) or Pleistocene Terrace 9.3%) deposits. River staining was absent from on cores from the Pleistocene Sands while 13 tools exhibit thermal alteration. Finally, a significant percentage of cores from the Pleistocene Sands are fragmented, possibly resulting from testing to evaluate tool–stone quality.

A total of 64 cores were identified from the Pleistocene Terrace (Appendix 35, Tables 7–25 to 7–27). These cores are similar in morphology to cores from the Pleistocene Sands, although they are wider than cores from the other strata. Cores from the Pleistocene Terrace exhibit fewer exterior surface removal scars, although this difference is not statistically
significant (Table 7–26). These core tools predominantly have multidirectional removal scars and like examples identified from the Pleistocene Sands, are highly fragmented. Modification and retouch scars are few in number compared with core tools from the Pleistocene Sands.

**Biface Tools**

A total of 78 artifacts were classified as bifaces and broken bifaces (Table 7–24,25). When bifaces were tabulated by context, nearly all (95.18%) were recovered from the Archaic and Paleoindian deposits. These include 18 Middle to Late Archaic (MALA) bifaces (Figures A35–13 and A35–14), two Taylor projectile points (Figure A35–15), and 55 Clovis bifaces (Figures A35–16 and A35–17). Bifaces are considered the predominant tool form from the Holocene and terminal Pleistocene deposits on the Terrace at Topper.

Seven MALA bifaces were classified as finished points, while the remaining artifacts were categorized as preforms or broken fragments (Table 7–28). The mean morphological attributes of complete MALA bifaces are presented in tables A35–1 and Table 7–28. These artifacts are smaller than complete Clovis bifaces in all morphological categories with the exception of thickness. Of the MALA bifaces identified, eight were recovered from a cache that was designated Feature 48. When examined by condition, most MALA bifaces exhibit evidence of thermal alteration. Interestingly, bifaces from Feature 48 lack thermal alteration. Exterior surface removal scars on MALA less frequent than on Clovis bifaces. In addition to the complete MALA bifaces, three MALA point bases and two tips were also identified, although an examination for the potential of refits among these artifacts was not successful.

Fourteen complete biface preforms and 41 biface fragments were identified from the Clovis deposits from the study sample. Technological and Morphological attributes of these

artifacts are presented in Table A35–1 and Table 7–28. Morphologically, complete Clovis bifaces are larger than those from other contexts at Topper. Smallwood (2010) found two size ranges for Clovis preforms at the Topper Site based on an analysis of 174 bifaces identified from the site. All but 20 were identified from the buried Topper hillside deposits. The larger morphological grouping has lengths and widths that “range from 115.0 to 144.80mm and from and from 55.1 to 56.2 mm, respectively” (Smallwood 2010:2417). By contrast, small preforms are “variable and range from 38.2 to 84.5 mm and widths vary between 22.3 and 41.9 mm” (Smallwood 2010:2417). Based on these findings, the Topper Clovis bifaces identified and examined for the present analysis from the Pleistocene Terrace are more similar in morphology to the small, variable grouping identified by Smallwood (2010).

Complete Clovis bifaces may be characterized as having multidirectional exterior surface removal scars with scar counts that typically exceed 20 in number, and tertiary, or lacking evidence of cortex. When examined by condition, all but four complete bifaces are interior, and completely lacking in cortex. The presence of thermal alteration was not observed on complete Clovis biface preforms from the study sample. Biface fragments exhibit multidirectional removal scars on the artifact exterior and scar counts that typically exceed 15. Unlike complete Clovis bifaces, a relatively high proportion of broken bifaces retain cortex on the exterior surface (25 of 41 or 60.9%). Moreover river staining and thermal alteration were more prevalent on broken specimens (Table 7–28).

Artifacts classified as bifaces from the Pleistocene Sands and Pleistocene Terrace consist of a single example and two flake fragments with bifacial flaking present on the exterior margin of each specimen. The single biface was recovered from the Upper Pleistocene Sands and is illustrated in Figures 7–2 and A35–17. This biface was recovered from unit N245.78 E138.20 at
Figure 7–2
Biface from the Pleistocene Sands at the Topper Site (38AL23). N245.78 E138.2 at a depth of 97.765m
a depth of 97.765m approximately 20cm below the primary concentration of Clovis deposits from the study sample. The biface measures 55.8mm long and is in 37.76mm wide, and 13.4mm thick. This particular biface is interesting in that it was isolated and recovered below other materials attributed to the Clovis culture, but well above the potential pre Clovis materials from the Pleistocene Sands. Morphologically, the biface appears similar to projectile points recovered from the pre Clovis deposits at the Cactus Hill Site in Virginia, albeit lacking a concave base (McAvoy and McAvoy 1997). However, Smallwood has also noted that Clovis preforms at Topper can come in small sizes and “the production of small performs and other types of bifacial tools suggest Clovis people in the region adjusted the bifacial components of their toolkit and adapted to more variability in toolkit design” (Smallwood 2010:7). Using the flaking index developed by Miller and Smallwood (2010), which is a ratio of the total number of flake scars from both faces to the corresponding bifacial edge length, the biface from the study sample produced a value of .32. According to Smallwood’s analysis, this flaking index value falls within the mean range of middle to late stage bifaces manufacture at Topper. At present, the precise age of the biface cannot be determined with certainty.

The two biface fragments from the Pleistocene Sands are considerably smaller than Holocene and Clovis bifaces. The morphological attributes of these fragments are presented in Table A35–1. River staining is present on one of these biface fragments. Technologically, this specimen is similar in form to bifaces recovered from Early Archaic contexts at the site, and may therefore represent redeposition or artifact displacement. Removal scars on the bifacial fragments recovered from Pleistocene contexts range from 9 to 12 with a mean of 10.5 scars per biface. Complete bifaces were absent from the Pleistocene Terrace although a single bifacially worked flake fragment was identified.
**Flake Tools**

Flake tools (n = 522) make up the largest tool class of the morphological typology at Topper (Table 7–24). Flake tools are flakes that have been modified by some means of further chipping or flaking. For this analysis, a number of tool categories are subsumed under the flake tool category and include utilized flakes, scrapers, and blades. The morphological attributes of flake tools are illustrated in Tables A35–18 to A35–33.

A utilized flake is defined as a flake that has flake scars resulting from use that extend less than 2 mm from the edge of the tool. Such removals can be but are not necessarily regularized and continuous along the edge of the flake margin. Scrapers are defined as flakes that display regularized edge retouch to produce a uniform and continuous edge along the flake margin. For simplicity, items classified as choppers and denticulates, although possibly serving an alternative function, were included within the scraper category. Blades are defined as any lithic detachment with two or more parallel removal scars on the exterior surface originating from the same plane or surface, and are usually twice as long as they are wide. Utilized flakes, scrapers and blades were recovered from all stratigraphic units at Topper, albeit in different proportions.

Interestingly, most flake tools (48.85%) at Topper were recovered from the Pleistocene Terrace, with fewer flake tools identified from the Pleistocene Sands (36.01%) and Clovis (15.13%) deposits (Table 7–24). However, when the distribution of flakes tools was compared by volume, on average, more flake tools were recovered from the Clovis deposits (1.33 flake tools per level) than from the Pleistocene Sands (.60 flake tools per level) or Pleistocene Terrace (.75 flake tools per level). Although the number of flake tools increases from the Clovis through the Pleistocene Sands, there is a decrease in the proportion of flake tools per level across this
interval. In the section that follows the morphological and technological attributes of flake tools from each depositional unit at Topper are discussed.

**Clovis Flake Tools**

The distribution of Clovis flake tools is presented in Table 7–29 and examples illustrated in Figure A35–18 through A35–20. The morphological attributes of Clovis flake tools are presented in Tables A35–2 and 7–30. The blades include eight complete examples and nine fragments including two distal fragments, three medial sections, and four blade proximal sections. Clovis blades from the study sample are short (52.13mm) compared with Topper blades that have been described from the Hillside portion of the site (61mm) (Sain 2011). Technological attributes that characterize the Clovis blade assemblage include exterior surfaces that are predominantly secondary or tertiary in form with removal scar patterns that are unidirectional. Scar counts typically exceed four and termination types are nearly exclusively feathered. When examined by condition, a single complete blade was found to have evidence of post detachment modification. Attributes of retouch on blades and other categories of flake tools are presented in Table A35–2. An additional four blade fragments have retouched margins and average 3.5 retouch scars per specimen. River staining was present on a small percentage (17.6%) of Clovis blades.

A total of 30 flake tools from the Clovis deposits were classified as scrapers (Figures A35–18 and A35–19). Morphologically, Clovis scrapers are larger than blades or utilized flakes from the same stratum (Table 7–30). Technological attributes of Clovis scrapers include scar patterns that are predominantly multidirectional with 10 or more prior detachment scars. By definition, all scrapers exhibit evidence of lateral edge retouch. Most scrapers (77%) are

</table>
modified on the exterior surface of the lateral margin of the flake. The remaining 23% of scrapers exhibit modification on the interior surface. Technologically, a total of 16 scrapers were classified as end scrapers and 14 are side-scrapers. Attributes of retouch on Clovis scrapers are presented in Table A35–2. The frequency of retouch on scrapers is higher than was found to occur on Clovis blades or utilized flake tools. When examined by condition, a relatively high proportion of scrapers from the Clovis deposits exhibit thermal alteration. A single scraper exhibited river staining.

A total of 32 Clovis artifacts were classified as utilized flakes (Table 7–29). Morphologically, utilized flakes are smaller that Clovis blades or scrapers (Table 7–30). Unlike blades, Clovis utilized flakes have exterior surface removal scars that are predominantly multi-directional. Total scar counts on Clovis utilized flakes are fewer in number than found on blades or scrapers. An examination of the presence or absence of lateral edge modification shows that nine utilized flakes have multiple flake margins that exhibit modification. Retouch scars on utilized flakes occur in greater frequency than found on blades, but less than observed on scrapers (Table A35–2). When examined by condition three utilized Clovis flakes were found to have river staining on the flake exterior. Only a single flake has thermal alteration (Table 7–30).

**Pleistocene Sands Flake Tools**

There are 188 flake tools from the Pleistocene Sands (Table 7–29). These tools were further classified as either blades, scrapers, or utilized flakes. Figure A35–21 presents a sample of blades identified from the Pleistocene Sands. The piece plotted blade assemblage from the Pleistocene Sands includes three complete blades, four distal fragments, one medial segment, and two proximal sections. In addition to the piece plotted items, numerous small blades were also recovered from the screen. A sample of these items are presented in Figure A35–22.
Morphologically, blades from the Pleistocene Sands are small, and are more similar in form to bladelets (defined as blades smaller than 50mm in length) (Table A35–3). The morphological attributes of blades from the Pleistocene Sands are presented in Table 7–30. Complete blades from the Pleistocene Sands demonstrate a decrease in size compared with blades identified from the Clovis deposits. Technological attributes consistent with blades from the Pleistocene Sands include detachments that are secondary or tertiary removals, scar patterns that are predominantly unidirectional with fewer than three removal scars per blade, and feathered distal terminations as oppose to those that end in step or hinge fractures. A comparison of blade attributes from the Clovis and Pleistocene Sands shows that the items recovered from the Pleistocene Sands are not only smaller, but have fewer removal scars than blades from the Clovis deposits (Table 7–30).

An examination of the condition of blades from the Pleistocene Sands found few (n = 3) that have evidence of modification or retouch. Retouch (Table A35–3) was limited to the lateral margin of the blade and typically consisted of three to four retouch scars. Thermal alteration and river staining were absent on blades from the deposits.

A substantial assemblage of scraper tools were identified from the Pleistocene Sands (n = 52). Examples of scrapers from these deposits are illustrated in Figure A35–23 to A35–28. Artifacts classified as scrapers include 31 complete tools, and 21 scraper fragments. In terms of morphology, scrapers represent the largest flake tool class identified from the depositional unit (Table 7–30). Technologically, scrapers from the Pleistocene Sands have removal scars that are nearly exclusively multi–directional. Only a single example has uni–directional removal scars and was produced on a flake distal fragment. This pattern differs from the attributes observed on scrapers from the Clovis assemblage which frequently have unidirectional scar patterns. When examined by cortex, most scrapers were made on secondary detachments while the remaining
artifacts are tertiary. The high incidence of partial cortex on scrapers from the Pleistocene deposits is indication that tools were completed prior to the total removal of all cortex from the artifact exterior. Further examination of the exterior surfaces of these scrapers found that scar counts are fewer in number compared with items from the Clovis deposits (Table 7–30).

Figures A35–25 to A35–28 show scrapers that have visible evidence of retouch or use. When examined for post detachment modification, all scrapers exhibited some form of retouch. The incidence of retouch on scrapers is similar to the frequency of retouch observed on scrapers from the Clovis assemblage (Table A35–2 and A35–3). A One Way Analysis of Variance Test (ANOVA) comparing the frequency of retouch scars for each assemblage shows that the two assemblages are not statistically different (df = 1; F = .00015; p value = 0.9901) (Table 7–31). When attributes of artifact condition were considered, a total of two scrapers were found to exhibit thermal damage in the form of potlids. River staining is absent on scrapers from the Pleistocene Sands (Table 7–30).

Utilized flakes comprise the largest assemblage of flake tools (n = 126) from the Pleistocene Sands. Interestingly, a high proportion of the utilized flakes from these deposits were broken or fragmented. A sample of fragmented utilized flakes is illustrated in Appendix 35. Most utilized flake tools (n=99) are flake fragments, whereas only 27 are complete. Utilized flakes from the Pleistocene Sands are larger in size than tools recovered from the Clovis deposits (Table 7–30).

When utilized flakes from the Pleistocene Sands were examined by the condition and frequency of prior detachment scars, most items have multidirectional removal scars. Most utilized flakes have partial cortex on the flake exterior (n=86) and are secondary flakes. A total of 39 flakes are tertiary and a single example is entirely cortical. A total of 74 utilized flakes

have retouch scars. Retouch scar counts on utilized flakes range from 3 to 24 with a mean of 6.11 scars per item (Table 7–30). Accordingly, there is little difference in the frequency of retouch scars on utilized flakes when the Clovis and Pleistocene Sands assemblages are compared. When examined by condition, two utilized flakes are thermally damaged, and a single artifact exhibits river staining on the exterior surface.

A number of intriguing patterns were revealed when flake tools from the Pleistocene Sands were compared with tools from the same artifact class from the Clovis deposits. In terms of morphology, Clovis blades are larger than blades from the underlying Pleistocene Sands assemblage (Table 7–30). However, this pattern is reversed when the piece plotted Scraper and Utilized flake assemblages are considered. Artifacts from the Pleistocene Sands are larger and heavier than similar tool forms from the Clovis deposits. Based on the differential sizes of artifact types between the two assemblages, it is unlikely that the entire flake tool assemblage from the Pleistocene Sands resulted from bioturbation.

Patterns are also revealed when the technological attributes of the Topper Clovis and Pleistocene Sands flake tool assemblages are compared (Table 7–30). With the exception of utilized flakes, Clovis flake tools, on average, have a greater incidence of prior detachment scars that flake tools identified from the deeper deposits. This pattern could indicate that the tools from the Clovis assemblage were being reduced to a later stage of the reductive trajectory than tools from the Pleistocene Sands. Moreover, these findings could also indicate that greater time and effort were applied in the production of Clovis flake tools than was the case in the production of flake tools from the Pleistocene Sands. A comparison of scar counts on utilized flakes shows that scars on items from the Pleistocene Sands are slightly greater in number than Clovis utilized flakes, although this difference is not significant (Table 7–30).
assemblage were compared by degree and extent of modification, no statistical difference was observed in the frequency of retouch scars, although blades from the Clovis deposits tend to have slightly higher retouch scar counts (Table A35–2,3).

An attribute that distinguishes the Clovis and Pleistocene Sands flake tool assemblages is the general lack of river staining observed on the cortex of flake tools from the Pleistocene Sands deposits. Approximately 8.8% of the flake tools from the Clovis deposits exhibit river staining on the exterior surfaces of flake tools. In contrast, river staining was only found on a single item or less than 0.5% of flake tools from the Pleistocene Sands. These findings could indicate that river–stained cherts were not available at the time the Pleistocene Sands were deposited. It is also possible that weathering has obscured the presence of river staining on flakes from the Pleistocene Sands. The latter scenario, however, implies that weathering processes should also obscure the presence of upland cortex on flake tools from the Pleistocene Sands. To account for each possibility, the distribution of flake tools by cortical type was examined. The results, (Table 7–32) show that upland cortex was identified on a significant proportion of tools from the Clovis and Pleistocene Sands. Given these results, it is unlikely that weathering processes have obscured all evidence of river staining that could have formed on items deposited in the Pleistocene Sands, and the more plausible conclusion is that river–stained cherts were not exposed at the time the Pleistocene Sands were deposited.

**Pleistocene Terrace Flake Tools**

The morphological stone tool analysis resulted in the identification of 255 flake tools from the Pleistocene Terrace (Table 7–29). This number equates to a proportion of 0.75 flake tools per 5cm excavated level from the units examined for the study sample (number of tools = 255 / number of excavated 5cm levels 1x1m² = 340) (Table 7–25). Flake tools from the
Pleistocene Terrace were separated according to three artifact categories consistent with the Clovis and Pleistocene Sands deposits; blades (n = 13), utilized flakes (n = 211), and scrapers, (n = 31) (Table 7–30). These artifacts are illustrated in Figures A35–36 and A35–37. Table 7–31 presents the morphological attributes of flake tools by type for the Pleistocene Terrace. By total quantity, blades make up the lowest proportion of flake tools identified from the Pleistocene Terrace. Morphologically blades are small. Compared with blades from the overlying deposits, examples from the Pleistocene Terrace (Figure A35–30) are small and are more similar in form to bladelets than to technological blades. Interestingly very few blade cores were identified from the Pleistocene Terrace deposits which might have been associated with blade production at the site.

When blades were examined by the condition of the exterior surface, most (n = 7) items were classified as tertiary blades. Four secondary and two decortication blades were identified. The removal scars on secondary and tertiary blades are predominantly unidirectional (n = 10), with bidirectional and multi-directional forms occurring with less frequency (n = 3). Scar counts on blades are presented in Table 7–30 and occur with less frequency than removal scar counts on Clovis blades. When distal terminations types were examined, most blades had feathered terminations (n = 8) with step terminations less common (n = 5). No blades from the Pleistocene Terrace have hinge terminations.

An examination (Tables 7–30, A35–2 to A35–4, and Appendix 37) of the condition of blade tools from the Pleistocene Terrace resulted in a number of intriguing findings. For example, a slightly higher proportion of blades from the Pleistocene Terrace were found to have retouched margins (30.76%) than blades identified from the overlying Clovis (28.12%) or Pleistocene Sands (30%). Blades from the Pleistocene Terrace (Table A35–2 to A35–4) average
higher retouch scar counts than blades from the Pleistocene Sands and values are comparable to examples identified from the Clovis deposits. Moreover, retouch on all Pleistocene Terrace blades is exclusive to the exterior blade margin whereas at least a portion of blades from other deposits exhibit retouch on both the exterior and interior margins.

The Pleistocene Terrace scraper assemblage (Table 7–29) includes twenty three complete tools and eight broken or fragmented tools. Most complete examples were classified as end scrapers having retouch along the distal or proximal terminus of the tool as opposed to retouch along the lateral margins. Figures A 35–31 and A35–32 present selected end scrapers from the Pleistocene Terrace with retouch while Table 7–30 presents the morphological characteristics of the Pleistocene Terrace scraper assemblage. Pleistocene Terrace scrapers are comparatively small. The largest examples rarely exceed 100mm long and most (n = 20) are less than 20mm long. In terms of morphology, Pleistocene Terrace scrapers are more similar in size to Clovis scrapers and are significantly smaller than similar items from the Pleistocene Sands.

All Pleistocene Terrace scrapers were examined by technological attributes of the exterior and interior surfaces (Results obtained from Appendix 31–32). Scrapers from the Pleistocene Terrace are characterized as a product of secondary detachments, are fragmented, and have multidirectional removal scars on the exterior tool surface. Only a single example is entirely cortical. Accordingly, these items are comparable to scrapers recovered from the overlying deposits in terms of the presence and amount of exterior surface cortex. Scrapers from the Pleistocene Terrace tend to have significantly fewer removal scars than similar tools identified from the Clovis or Pleistocene Sands (Table 7–30).

When examined for the presence of post detachment modification, all scrapers from the Pleistocene Terrace exhibited some retouch. The incidence of modification found on scrapers
from the Pleistocene Terrace assemblage occurred in a much lower frequency than on items from the overlying deposits (Table A35–4). Moreover, examination of the nature of retouch scars shows that many are irregular in form, occurring intermittently and non-uniformly along the tool margin. It should be noted that modification typically considered the result of cultural processes usually consists of two or more uniform, parallel retouch scars taken from a given margin of the tool edge. The low incidence of retouch found on these tools combined with the smaller tool morphology calls into question whether retouched margins on scrapers from the Pleistocene Terrace were actually the product of natural as opposed to cultural formation processes.

A total of 211 utilized flakes were identified from the Pleistocene Terrace deposits at Topper. When examined by completeness the majority of utilized flakes are incomplete or broken fragments (n = 168). Only 43 complete utilized flakes were identified from the Pleistocene Terrace deposits. Figure A35–33 and A35–34 presents examples of utilized flakes from the Pleistocene Terrace. The flake fragment in Figure A35–34 has utilization along the exterior lateral margin of the specimen. Utilized flake morphologies are presented in Table 7–30. The utilized flake assemblage from the Pleistocene Terrace represents the smallest tool class in terms of size compared with similar flake tools identified from the overlying deposits. Technological attributes of the Pleistocene Terrace utilized flake assemblage include exterior surfaces that exhibit partial cortex or are cortical, removal scar patterns that are multidirectional, and comparatively few prior detachment scars. A total of 19 of the 211 (9 %) utilized flakes are entirely cortical. By contrast only two utilized flakes from the Pleistocene Sands and two examples from the Clovis deposits are cortical. Most Pleistocene Terrace flakes are secondary (n = 133). Although predominantly multidirectional, utilized flakes from the Pleistocene Terrace also have a high frequency of scar patterns that are uni–directional (n = 73 or 36.68%) compared
to similar flake tools identified from the overlying deposits (Pleistocene Sands = 20%; Clovis = 25.80%). Utilized flakes from the Clovis and Pleistocene Sands deposits have higher mean scar counts, possibly indicating greater intensity in reduction. The results of a One Way Analysis of Variance show a statistical difference in the frequency of removal scars on utilized flakes by depositional unit (df = 2; F = 8.08; p = 0.000389) (Table 7–31). When examined by termination type, most utilized flakes have feathered terminations (n = 122) although step terminations are also common (n = 65). Utilized flakes from the Pleistocene Terrace have a higher proportion of hinged terminations compared with the proportion of termination types observed on flakes from the overlying strata. An analysis (Table 7–30) of the presence or absence of thermal alteration shows that 19 or 9.0% of utilized flakes from the deposit present evidence of thermal alteration. Most examples appear to take the form of thermal damage, pot–lidding or crazing as opposed to intentional heat treatment. Retouch modification occurs on all utilized flakes. Compared with similar tools from the Clovis and Pleistocene Sands, items from the Pleistocene Terrace have significantly fewer retouch scars (Table A35–4). Based on the morphological, technological, and conditional attributes of flake tools, items from the Pleistocene Terrace in general have fewer attributes of utility compared with tools from the Clovis and Pleistocene Sands.

**Bend Break Tools**

Based on the morphological typology, 283 piece plotted bend breaks were identified from the study sample (Table 7–2). All but eight of these bend breaks were recovered from the Pleistocene Sands (n = 39) and Pleistocene Terrace (n=236) deposits. Figures A35–36 to A35–38 presents examples of bend break tools from the Topper Site. Of the Clovis bend breaks only two are modified. An inspection of the two examples from the Clovis deposits suggests that these
items are snapped or broken biface fragments that exhibit retouched margins, modified prior to snapping.

Of the 275 bend breaks identified from Pleistocene contexts, nearly half (123) exhibit some form of modification and are therefore classified as tools. Of these, 17 bend break tools were recovered from the Pleistocene Sands and 94 from the Pleistocene Terrace. Bend breaks from the Pleistocene Sands and Terrace at Topper fall into two technological categories; modified bend breaks, and bend break gravers. Tables 7–33 through 7–35 present the morphological and technological attributes of modified bend breaks and bend break graver tools. Bend break gravers are distinguished from modified bend breaks by a protruding “spur “chipped along one or more break margins to possibly serve the purpose of grooving or gouging materials. Figure A35–7 provides examples of modified bend break and a bend break graver.

From the study sample, a total of 99 items were classified as modified bend breaks and 24 were identified as bend break gravers. When this distribution was further examined by depositional unit, 81 of 99 (81.81%) modified bend breaks and 23 of 24 (95.8%) bend break gravers were recovered from the Pleistocene Terrace. As such, bend break graver tools are nearly exclusive to the Pleistocene Terrace. All modified bend breaks and bend break gravers from the Pleistocene Sands and Pleistocene Terrace were compared by morphological and technological attributes (Tables 7–33 to 7–35). Bend break tools from the Pleistocene Sands are often larger than tools from the Pleistocene Terrace (Table 7–33). However, the results of a t-test(Table 7–34) show that there is no statistical difference in the morphological attributes of Pleistocene Terrace gravers and bend breaks. Bend break graver tools from both deposits are predominantly cortical and have multidirectional removal scars. When scar frequency is compared by tool type and stratum, higher scar counts are found on items from the Pleistocene Sands regardless of tool

</table>
type (Table 7–35). However, when just the Pleistocene Terrace is considered, bend break gravers have higher mean scar counts than modified bend breaks. These patterns might reflect the greater reduction requirements necessary to produce bend breaks with graver spurs. An examination of the presence and amount of retouch on bend breaks supports these same patterns. Examples from the Pleistocene Sands, regardless of tool type, have greater incidence of retouch, whereas bend break gravers from the Pleistocene Terrace average higher quantities of retouch scars than artifacts classified as modified bend breaks.

In addition to the incidence of retouch, all bend break tools were examined by the frequency of 90° break angles. Such angles are thought to have served as useful cutting or perforating tools (Goodyear Personal Communication). As such, artifacts with more break 90° angles would have also been of greater utility. The results of analysis show that most bend break tools (modified and graver) have 90° break angles that range in number from two to five (see Appendix 37). A comparison of the frequency of break angles on bend breaks by type (modified and graver) and stratum found no significant difference in break angle frequency by depth although modified bend breaks from the Pleistocene Sands have slightly higher mean break angles.

**Chopping Tools**

Apart from the tools presented in Table 7–24, 42 additional tools from the study sample were identified as chopping tools (Table 7–37). Choppers are similar to cores, but are defined as having flakes removed from a portion of their surface resulting in a sharpened edge useful for chopping, scraping, or cutting. Examples of choppers from the Topper Site are presented in Figures A35–to A38–43. All but two items classified as choppers were recovered from the Pleistocene Sands. These two items were recovered from the Upper Pleistocene Terrace. Table

7–36 presents the morphological attributes of choppers. Morphologically, choppers are comparable in size to cores but are on average slightly larger and therefore represent the largest of the artifact categories examined.

Technologically, chert choppers at Topper have two to five areas of the edge or margin that exhibit battering in the form of flake removals. Such removals are feather or step terminations and depend on the type of material being worked. The flake removals from a given area of the lateral margin of a chopper typically exceed six in number. Two choppers have additional attributes including chipped or notched areas on the chopper surface that would have allowed the object to be secured in hand. The choppers in Figures A35–39 and A35–40 present two examples of artifacts that have chipped surfaces.

Production Tools

There are 63 artifacts classified as production tools at Topper. Production tools include hammerstones, hammerstone fragments, and anvil stones. Anvils are lithic objects that have been used as a support for the load application produced when an objective piece is being struck. Hammerstones are stone percussors used to strike an objective piece, whereas hammerstone fragments are hammerstones that have broken during stone tool production. Examples of production tools recovered at Topper are illustrated in Figures A35–45 to A35–50.

The production tool class is rather evenly distributed through the stratigraphic profile at Topper. Most artifacts associated with tool production were recovered from the Clovis deposits (41.26%), with lesser proportions occurring in the Pleistocene Sands (31.74%) and Pleistocene Terrace (26.98%) (Table 7–24). The distribution of production tools can inform about potential strategies of lithic tool production at Topper. For example, anvil stones (n = 10) are found in Pleistocene Sands contexts associated with core and bend break tools and in the Pleistocene
Terrace contexts associated with bend break tools. Evidence for compressive force application is evident on the anvil stone depicted in Figure A35–45. This weathered specimen fractured near the point of impact. Similar concentric rings of force are evident on the items presented in Figure A35–46 from the Pleistocene Terrace.

While anvil stones comprise nearly half of all production tools identified from the Pleistocene Sands, these artifact forms are absent from the Clovis deposits. In contrast, hammerstones occur in greater frequencies from the Clovis deposits and to a lesser extent from the Pleistocene Sands and are associated with biface and flake tool production accordingly. Figures A35–47 and A35–48 show selected hammerstones and broken hammerstones recovered from the Pleistocene Sands. Hammerstones are infrequent from the Pleistocene Terrace, and examples that do occur tend on average to be smaller in size than items recovered from the overlying deposits.

One discovery from the Pleistocene Terrace is the occurrence of split quartz pebbles. A sample of split quartz pebbles recovered from the upper Pleistocene Terrace at the Topper Site (38AL23) is presented in Figure A35–50 and the distribution of mapped quartz pebbles is presented in Appendix 44. These items occur in abundance throughout the Lower Pleistocene Sands and upper levels of the Pleistocene Terrace and are frequently recovered in association with bend breaks. All but two of the examples are in Figure A35–50 from the Upper Pleistocene Terrace above elevation 96.00m. As the Pleistocene Terrace represents a fining-up sequence whereby larger sediment particles are expected from lower (deeper) deposits, one should also expect an increase in quartz pebble sizes as well as an overall larger quantity of pebbles at greater depths through the Pleistocene Terrace profile. The mass and size grade analyses in chapter 9 present the distribution of quartz by size. In contrast to expectations, a high quantity of
relatively large split quartz pebbles co-occur with the fine grained clayey sand sediments of the upper Pleistocene Terrace. The small clast size of the sediment deposits commonly reflects low-energy environments of deposition. Combined with the angular to subangular condition of quartz recovered from the upper Pleistocene Terrace, the probability that these items formed exclusively as the direct result of fluvial activity is low.

One possible explanation for the presence of split quartz pebbles is that they served as small anvils to aid in the bipolar flaking process; with the pebbles occasionally fracturing upon impact. In such instances, the split pebbles would subsequently be subsumed under the debitage category; a byproduct of the manufacture process. An inspection of a number of the split quartz pebbles from the Pleistocene Sands and Pleistocene Terrace at Topper shows evidence of impact markers at the point of breakage which would imply that they could have been incorporated into the pre Clovis toolkit, used and in some cases broken.

Fiedel (2013:344) suggested that some alleged pre Clovis reports cite low ratios of debitage to tool counts for pre Clovis deposits, compared to later assemblages. Fiedel (2013:344) questions why the “tool-making activities of pre Clovis knappers produce less shatter than later peoples”? The decrease in debitage frequency is thought by critics to indicate 1) down-drift of smaller debitage through time, and 2) that the perceived stone tools in early deposits are the product of natural breakage imitating human manufacture or retouch. To examine whether or not this observation holds true at Topper, the tool-to-debitage ratios were calculated for each assemblage category. For comparative purposes, split quartz pebbles were included as a separate debitage category (Appendix 44), and evaluated relative to the distribution of bend breaks from each depositional unit. An inspection of the frequency of tool forms to potential production artifacts for each depositional unit reveals a number of notable patterns. The results of this
analysis are presented in Figures A35–9 and A35–10. There is a decrease in bifaces through the profile relative to the distribution of complete flakes (fewer tools, more flakes). This means that either the flakes are filtering through the profile, or that biface production was not being actively carried out at the site prior to the Clovis occupation. By contrast, bend breaks significantly increase throughout the profile relative to the number of complete flakes (more tools, fewer flakes).

The ratio of bend breaks to debris is similar when the Clovis and Pleistocene Sands deposits are compared, with fewer tools than debris. However, there is an increase in the number of bend breaks to debris in the Pleistocene Terrace (i.e. more tools, less debitage). When split quartz pebbles were examined, the ratio of bend breaks to quartz pebbles (>2.5 cm in diameter) was found to be close to 1:1 for the Clovis and Pleistocene Sands units. However, there are significantly more bend breaks and quartz pebbles in the Pleistocene Sands than in the Clovis deposits, although not so many as to fall outside the range of what might be expected of a typical lithic workstation. The proportion of quartz pebbles greater than 2.5 cm increases in the Pleistocene Terrace where the ratio of split quartz pebbles to bend breaks is closer to 2:1 (more debitage, fewer tools) (Table 7–24). Based on these patterns, there is no evidence to suggest that quartz could not have been employed as a tool production implement; particularly in the lower Pleistocene Sands and possibly the Upper Pleistocene Terrace. Further examination is required to determine if there is an association between bend break manufacture and the use of quartz as a production implement. Chapter 11 examines this possibility in greater detail.

*Stone Tool Analysis: Interpretation and Summary*

The distribution of chipped stone tools at Topper can potentially inform about differential strategies of tool production through time. When the distribution of each of the five tool types is
examined in detail (Table 7–24) a number of patterns emerge. For example, core tools are most abundant from the Pleistocene Sands and to a lesser extent from the Pleistocene Terrace. Biface tools are nearly exclusively found in the Holocene and Clovis deposits. Flake tools are predominantly recovered from the Pleistocene Terrace and the Pleistocene Sands. Bend break tools are also primarily a product of the Pleistocene Terrace but are rare in the Clovis deposits. Finally, production tools are evenly distributed throughout the depositional contexts at Topper, but depending on type can potentially inform about the types of tools that they were used to produce.

The results of the morphological typology demonstrate distinct patterns in the toolkit composition for each depositional unit at Topper and allow for the reconstruction of chipped stone tool technologies at the site. Clovis peoples were primarily focused on biface manufacture and to a lesser extent flake core production. There is little evidence for bifaces in the lower deposits at Topper implying that if there was a pre-Clovis occupation at the site, then people were employing alternative lithic production technologies for the manufacture of stone tools.

The tool assemblage from the Pleistocene Sands reflects lithic technological strategies centered on core and flake tool manufacture and the use of bipolar production for the manufacture of bend breaks. The Pleistocene Terrace is dominated by bend breaks, and if these items are in fact a product of human agency, then they reflect a bipolar and compression flaked stone technology geared toward the production of bend break tools. The combined results of the morphological typology indicate a clear dissimilarity in toolkit composition at Topper between the Clovis and pre-Clovis deposits. If the lithic assemblages from the Pleistocene Sands and Pleistocene Terrace are cultural, then the results suggest that at least two human populations, separated in time, were utilizing the chert outcrop at Topper for different technological strategies.
of tool production at the site. However, natural processes can also produce attributes on lithic materials that could mimic those associated with chipped stone tool production technologies. To determine if natural processes were responsible for the occurrence of bend break flakes from the Pleistocene deposits at Topper, an experimental program was undertaken that examines the effects of various weathering agents on lithic materials. The results of this study are presented in chapter 8.

** Modification and Lithic Microwear Analysis**

A sample of items from the lithic assemblage at the Topper Site was examined for the presence of modification. For this study, two separate analyses were conducted. These analyses include a macroscopic edge modification analysis to evaluate whether the presence of edge modification on proposed chipped stone tools resulted from human use versus natural processes. Importantly, this study was employed to determine the technological attributes that are preferred for tool use. A second analysis included a microscopic microwear examination to determine if the pre Clovis assemblage consisted of utilized tools, and if so, what function or purpose such tools might have served.

**Index of Modification**

For the macroscopic approach Andrefsky’s Index of Modification, or IM (Andrefsky 2013) (IM) was employed and accounts for the number of segments of an artifact that have been modified. The artifact is first placed under a grid containing eight segments. If retouch is visible within or on a margin of the artifact within a given segment, it is recorded. The total number of segments with modification is subsequently tallied. Figure 7–3 illustrates an example of the IM analysis. According to Andrefsky (2013), edge modification attributed to human use typically occurs within a range of 2 to 5 segments of the artifact. By contrast, artifacts with two or fewer
Figure 7–3

Images showing A; a chert scraper from the Pleistocene Sands with cultural retouch indicated by blue lines and B; a chert flake fragment from the Pleistocene Sands with naturally produced retouch highlighted. Natural retouch is less patterned, infrequent, and not as well-defined as cultural retouch.
segments or greater than 5 segments of modification are considered as byproducts of natural or
post depositional processes. Figure 7–4 illustrates retouch on two artifacts from the Pleistocene
Sands; one artifact, a scraper, has modification in the form of retouch on the end of the tool
(Figure 7–4a). The modification is uniform and consists of more than three consecutive parallel
retouch flake removals at the distal end of the tool. This artifact is evidence of cultural
modification. In contrast, a chert flake also has removals along the distal end of the artifact but
they are fewer in number, less uniform, and irregular in form (Figure 7–4b). The visible chipping
on the flake is more likely evidence of modification incurred as the result of natural processes.

A total of 370 lithic items from the study sample were examined for the IM analysis.
Table 7–37 presents the descriptive statistics for the distribution of modified artifacts by
depositional unit. Based on the mean IM values, artifacts from each depositional unit at Topper
fall within the range attributed to human modification. However, artifacts from the Clovis and
Pleistocene Sands have higher mean IM values than do items from the Pleistocene Terrace. The
results of a One Way Analysis of Variance test (ANOVA) show that the difference between the
means is statistically significant and that the probability of this result by chance is less than
.0001. (df = 2; F = 25.01; P = < 0.00001) (Table 7–38). To gain a better understanding of the
results of the IM, the distribution of modified artifacts from each depositional unit were
compared by type, technological attributes of the artifact exterior and interior surface, condition,
and morphological attributes of length width and thickness.

Clovis

A total of 37 Clovis artifacts were examined for the presence and extent of modification,
yielding a mean IM value of four (Table 7–37). A total of 33 of 37 artifacts have IM values that
exceed two and 20 have values that exceed four (Table 7–39). Clovis artifacts identified from the

IM analysis include 24 flake tools, three core tools and four biface tools. The distribution of modified Clovis debitage was further examined by interpretation categories (Table 7–40). Most modified debitage was found to fall within the flake fragment category with fewer items classified as broken flakes, debris, and amorphous debris. Complete flakes and broken flakes have higher mean IM values than items classified as flake fragments, debris or amorphous debris. These results imply that complete flakes exhibit a greater incidence of modification than items from the non–flake category.

When the distribution of modified artifacts was examined by morphology, longer items were found to typically have a higher IM value than items less than 50mm in length (Table 7–42). The results of a Pearson’s correlation analysis comparing modified Clovis flake length by IM value found a weak positive relationship between these two attributes ($R = 0.4667; R^2 = 0.2178$) (Table 7–42). Likewise an analysis comparing the distribution of modified Clovis flakes by cortical class shows that the incidence of modification decreases with increasing reduction intensity (Table 7–40). Cortical and secondary flakes have higher mean IM values than interior/tertiary flakes. However, the opposite pattern is found when modification by scar frequency is considered. Flakes with more than 10 removal scars on the exterior surface have more than twice as many retouch scars as flakes with fewer than 10 exterior surface removal scars. When examined by condition, a higher incidence of modification was found on flakes that have multi–directional as opposed to uni–directional removal scars, and on flakes manufactured from river stained chert. Given these findings, the Clovis items best suited for use are those that are longer than 50 cm in length and show evidence of care taken in the manufacture process demonstrated by high exterior surface scar counts.

350
Pleistocene Sands

There are 147 modified lithic items from the Pleistocene Sands. According to Table 7–38, modified tools from these deposits have a lower mean IM value than found on modified flakes from the Clovis deposits. However, the results of a t-test comparing the IM values for Clovis and Pleistocene flakes found no statistical difference between the two samples (Table 7–43).

When examined by frequency, most artifacts from the Pleistocene Sands have IM values that range between 2 and 5 (Table 7–39). Artifacts that fall outside of this range typically consist of amorphous debris, debris, or flake fragments. An evaluation of the distribution of flake types by modification shows that items classified as flakes have higher IM values than items from other flake categories (Table 7–40). For example, items classified as flake fragments, broken flakes, debris, and amorphous debris have successively lower IM values than flakes. These patterns are similar to the results found on modified items from the Clovis deposits. The abundance of modified complete flakes with IM values between two and five suggests an emphasis on the utilization of these items over those classified as flake fragments and debris.

When the distribution of modified artifacts was examined by morphology, the items that were less than 50mm in length have IM values that are lower than modified artifacts that are longer than 50mm (Table 7–42). The results of a Pearson’s correlation analysis comparing flake length by IM for flakes from the Pleistocene Sands shows a weak positive relationship between these two attributes (Table7–42).

All modified artifacts from the Pleistocene Sands were examined by technological attributes of the exterior and interior surface. An evaluation of the extent of cortex on artifacts by the IM value shows that higher values tend to occur on interior and secondary flakes than they do on cortical flakes. These findings are intriguing given that this is the opposite pattern from that
identified from the Clovis deposits where cortical and secondary flakes have higher modification values. When modified flakes were examined according to scar frequency, the flakes with more than 10 exterior surface removal scars were found to also have a higher mean IM values than flakes with less than 10 removal scars. This pattern is similar to the results identified on flakes from the Clovis deposits.

The scar patterns on modified flakes are predominantly multi-directional, with bi-directional and uni-directional scar patterns occurring with less frequency (Table 7–40). The results of an analysis comparing flake scar directionality by IM demonstrate a comparatively high mean IM value on multi-directional flakes from the Pleistocene Sands (Table 7–40). Flakes with uni or bi-directional scar patterns have mean IM values that are on average, lower than values found on flakes with multi-directional scar patterns. However, the difference between these means is significantly less than was found to distinguish multi-directional and uni-directional flake patterns on items from the Clovis deposits. Unlike items from the Clovis deposits, all modified flakes from the Pleistocene Sands lack evidence of river staining, apparently a critical attribute used to distinguish lithic items between the two depositional units.

**Pleistocene Terrace**

A total of 275 modified lithic items were identified from the Pleistocene Terrace and underwent the IM analysis. The modified Pleistocene Terrace artifacts include 152 flake tools, 49 bend break tools and 20 core tools. The frequency of all modified Pleistocene Terrace artifacts was tabulated by interpretation free flake categories (Table 7–40). Fifty six items lacked discernable retouch scars and were excluded from this analysis. Accordingly, most modified items were classified as debris. Less than 10% of the population is made up of broken or complete flakes. However, when the mean IM values are compared by interpretation free
category (Table 7–40) items classified as flakes and flake fragments have higher mean IM values than items classified as debris, amorphous debris, or pebbles. When examined by frequency, most modified artifacts from the Pleistocene Terrace have IM values that range between 2 and 5. Additional analysis shows that the majority of these artifacts were classified as debris with lesser amounts having attributes classified as amorphous debris, flake fragments, or flakes. Artifacts that fall outside of this range typically consist of debris, amorphous debris, or flake fragments.

Table 7–41 presents the distribution of modified artifacts for each depositional unit by the IM value. According to the table, modified artifacts from the Pleistocene Terrace that have IM values between 2 and 5 are predominantly composed of debris or amorphous debris, whereas greater percentages of artifacts from the Clovis and Pleistocene Sands were classified as flakes and flake fragments. It appears that the percentage of modified items classified as debris or amorphous debris increases with depth whereas the opposite pattern is true for items classified as flakes and flake fragments. Moreover, when the artifacts with IM values < 2, or > 5 were considered, most artifacts were classified as debris, amorphous debris, or pebbles. These patterns demonstrate a correlation between the IM value, artifact location of origin, and the assigned interpretation free category. The relatively high proportion of modified debris from the Pleistocene Terrace deposits that have IM values less than two is suggestive of modification by natural rather than cultural processes.

All modified artifacts from the Pleistocene Terrace were examined by morphology (Table 7–42). Longer items typically have a higher IM value than items that are less than 50mm in length. Subsequently, all modified artifacts from the Pleistocene Terrace greater than 50mm in length were compared by the IM value to artifacts of similar morphological thresholds from the overlying deposits. The modified artifacts from the Clovis and Pleistocene Sands have higher IM
values than artifacts from the Pleistocene Terrace (Table 7–42). There is a decrease in the extent of modification observed on larger items as depth increases at the site.

An examination of the technological attributes of the exterior and interior surfaces of modified artifacts from the Pleistocene Terrace resulted in a number of intriguing findings (Table 7–40). Artifacts with cortex have lower IM values than artifacts that lack cortex. A comparison of the mean IM values for cortical class by depositional unit shows that items from the Clovis and Pleistocene Sands have higher mean IM values regardless of cortical class than do items identified from the Terrace. These findings imply that the modification observed on items from the higher deposits is more likely to have been the product of human agency than the relatively low values observed on artifacts recovered from the Pleistocene Terrace.

While the overall IM values are lower for items recovered from the Pleistocene Terrace compared to items recovered from the Pleistocene Sands, the two depositional units share the same general trend; that is an increase in IM value with decreasing rates of cortex (Table 7–40). However, compared to the Clovis deposits, the opposite pattern is evident. The IM values are highest on secondary flakes and lowest on interior specimens. These patterns imply that Clovis peoples were selecting the longer, secondary artifacts for use as tools. It should be noted that the results from the Clovis deposits are based on a much smaller sample size (n = 25) than the samples examined from the underlying deposits.

In addition to cortex, all modified items from the Pleistocene Terrace were evaluated by the number and directionality of prior removal scars (Table 7–40). The flakes with more than 10 removal scars also have IM values that are higher than items with fewer than 10 removal scars. This pattern is similar to the results found for artifacts recovered from the overlying Clovis and Pleistocene Sands. When flake scar directionality was considered, flakes with multi-directional
scars were found to have higher mean IM values than flakes with bi-directional or uni-directional patterns.

A comparison of the mean IM values by scar directionality for the Clovis, Pleistocene Sands, and Pleistocene Terrace samples show a general decrease in IM value with depth (Table 7-40). These findings support the notion that artifacts from the Clovis and Pleistocene Sands, regardless of the scar patterning of the exterior surface, provide greater evidence for cultural modification than do the items identified from the Pleistocene Terrace. Unlike items from the Clovis deposits, all modified flakes from the Pleistocene Terrace lack evidence of river staining. To summarize the results of the IM analysis, artifacts that fall within the range of culturally modified flakes are present at Topper from all depositional units. However, a higher percentage of artifacts from the Clovis and Pleistocene Sands exhibit edge modification consistent with cultural retouch compared with items recovered from the Pleistocene Terrace.

*Edge Damage and Microwear Analysis*

Microscopic use wear analysis is a method often employed on items from an assemblage of chipped stone tools to identify tool function. This is accomplished by closely examining the working tool surfaces, margins, and edges with the aid of a low or high powered binocular microscope, and subsequently making interpretations based on the presence or absence of specific indicator variables such as polish, residue, or striations. The ultimate goal of microwear studies is to assess what kinds of wear could have been generated by specific types of activity (motion) and resistance.

Two prior microwear studies have been conducted on lithic items from the pre Clovis deposits at the Topper Site. In 2001 and 2002 Dr. Marvin Kay examined a sample of 50 possible tools selected by the project director, Dr. Albert C. Goodyear from the Pleistocene Sands.
Materials were selected that exhibited a low degree of weathering, since it has the potential to remove microwear traces. The results of this analysis only identified six artifacts with possible use-striae, and one with micro-plating (Kay 2002). Examples of trace microwear on Topper artifacts are presented in A37–1 and A37–2.

In 2007, a sample of eight lithic items from the Pleistocene Terrace and Pleistocene Sands were taken by Goodyear to Texas A&M University to undergo a microscopic analysis conducted by Jim Wiederhold. Included within this sample was the bend break graver from the Pleistocene Terrace illustrated in Figure A37–1. Microwear analysis on this item shows evidence of edge damage and striations (linear indicators) resulting from use. Although weathered in some locations, evidence of polish can be seen on the immediate edge with a suggestion of striations and step fractures that are visible possibly resulting from repeated scraping on a hard material. Microwear on a second bend break and a utilized flake are presented in Figures A37–2 and A37–3.

In addition to the 58 lithic items that have undergone microscopic microwear analysis from the Topper pre Clovis deposits to date, the present study involved the microscopic examination of an additional 50 artifacts for edge damage and use-wear that might be the byproduct of human agency. These items were arbitrarily selected from a sample of artifacts from the Pleistocene Sands and Terrace that had been identified in the field as blades, flake tools, and bend breaks, and in which the subsequent stone tool analysis confirmed these classifications. Tables 7–44 and 7–45 present the distribution of these artifacts by type and stratum. As is evident by the tables, most artifacts selected for analysis were classified as bend breaks, utilized flakes, or scrapers although a single blade was also examined. The tools examined include 24 artifacts from the Pleistocene Sands and 26 items from the Pleistocene Terrace.

Obs = Observances
For this analysis, three categories of use wear and one category of edge damage (micro-chipping) were investigated. The microwear categories include polish, striations (linear indicators), and residue. Polishing is defined in this study as a type of form–altering agent that smoothens the lithic surface by a combination of tensile stress and mechanical removal of materials on the artifact microtopography. Striations are microscopic linear features on the surfaces of lithic materials that indicate evidence of contact on the tool’s surface. Striations are also referred to as linear indicators and depending on orientation, can be used to reveal a tool’s use-trajectory and serve as signatures of different tool functions. Evidence for edge damage takes the form of micro-chipping and rounding along one or both lateral margins or an end of the artifact. Keely (1980) recognized various types of polishes that can form on an artifacts surface caused by different materials. Polish for example can result from working bone, wood, hide as well as other materials. Keely incorporated high-powered magnification studies (100x to 400 x magnification) to determine the various activities that a given tool was being used for based on the presence, condition, and appearance of different forms of polish on a tools surface. Residue is defined as deposits of material that adhere to lithic objects that can occur from natural or human processes.

Tables 7–44 and 7–45 present the results of the microwear analysis. Based on the analysis, microwear was observed on a substantial proportion of the artifacts examined. Wear patterns were identified on 41 of the 50 artifacts. Traces of microwear identified include polish, striae, micro-chipping and residue (Table 7–45). A total of 81 separate examples of microwear were identified on 41 of the artifacts examined. Polish was the most common wear pattern identified on artifacts from the site, observed on 33 artifacts. Micro-chipping was observed on 28 artifacts. Unlike these trace microwear conditions, the occurrence of residue was only identified
on 9 specimens. The incidence of microwear was examined on four artifact categories from two depositional units; the Pleistocene Sands and Pleistocene Terrace. Table 7–45 presents the distribution of microwear patterns observed on artifacts by artifact type. Of the 24 artifacts examined from the Pleistocene Sands, microwear was observed on all artifact types, occurring on 23 of the items examined. The single blade exhibited microwear in the form of polish and micro-chipping; however, evidence for residue and striae were not visible on this item. When all other artifact types were examined from the deposit, use-wear patterns were ubiquitous across the sample. However, a number of patterns were identified when the frequency of microwear by condition was considered relative to the proportion of artifacts examined. For example, of the seven scrapers examined, micro-chipping was found to be the most common form of microwear identified, occurring on 86% of artifacts from the sample. Micro-chipping is a variable that can inform about the relative hardness of specific substrates. Artifacts that exhibit micro-chipping are more likely to have been used on harder substrates than those items that lack micro-chipping. When scrapers were examined for the presence of striae and residue, these microwear traces were less commonly observed on these artifact forms. A similar pattern was identified when the utilized flake assemblage was examined. Greater than 80% of all artifacts identified as utilized flakes were found to have evidence of polish and micro-chipping. However, one characteristic that distinguished scrapers from utilized flakes was an evident increase in the percentage of utilized flakes that exhibit residue compared to the percentage of scrapers that exhibit this microwear condition. Combined with the high percentage of micro-chipping observed on scrapers, these findings suggest that scrapers were predominantly used on materials with hard or tough surfaces, and on items that infrequently leave behind traces of residue.
When the sample of bend breaks from the Pleistocene Sands was examined for microwear, the patterns of trace microwear were fairly evenly distributed by wear type for the study sample. However, the results do show lower percentages of polish and micro-chipping compared with the percentage of such patterns observed on other artifact categories. For example, polish, the most common form of microwear identified on bend breaks, was only observed on 60% of the sample. Although residue and striae were observed on bend breaks in lower proportions than polish and micro-chipping, such conditions were found to occur with greater frequency on bend breaks than on scrapers or utilized flakes. These results suggest that bend breaks may have been suitable for a greater variety of tool functions than other tool categories examined from the Pleistocene Sands whereas scrapers and utilized flakes may have been reserved for specialized tasks.

Of the 26 artifacts examined from the Pleistocene Terrace, trace microwear was observed on 18 artifacts (Table 7–28). Microwear was observed on 12 bend breaks, five utilized flakes, and a single scraper. The scraper was found to exhibit microwear in the form of polish and micro-chipping. Residue and striae were not visible on this item. These patterns are similar to the distribution of trace microwear observed on scrapers from the Pleistocene Sands. When the sample of utilized flakes was examined, a high proportion of artifacts were also found to exhibit polish and micro-chipping. However, there is an apparent decrease in the percentage of artifacts that exhibit these microwear patterns when the Pleistocene Terrace sample was compared to items from the Pleistocene Sands. Striae and residue were rare on utilized flakes, and were only observed on a single specimen.

A total of 20 bend breaks from the Pleistocene Terrace were examined for trace microwear. Of the artifacts examined, microwear was least visible on bend breaks. For example,
only 50% of the items examined had evidence of polish, and micro-chipping was only present on 20% of the items. Although striations were observed on 35% of bend breaks from the Pleistocene Terrace (the highest proportion for any artifact class), residue was only observed on a single specimen. Of the seven bend breaks that exhibit striae, polish was also observed in association with the direction of the striae, possibly indicating that the causal mechanisms for each attribute are related. An examination of the spatial distribution of these seven bend breaks shows that all were recovered from the upper 25cm of the Pleistocene Terrace. The eight bend breaks examined from the study sample that lack microwear were recovered from the lower Pleistocene Terrace deposits. Based on the proportion of lithic artifacts that exhibit trace microwear, it is apparent that the majority of items derive from the Pleistocene Sands and to a lesser extent from the Pleistocene Terrace.

One goal of the microwear analysis was to test the proposition that microscopic use-wear-like patterns were the product of fragmentation or post–depositional effects. Because it is possible that postdepositional processes can result in edge modification that might resemble the lateral margin of a culturally produced chipped stone artifact, it is essential that the microwear analyst distinguish the attributes resulting from natural processes from those that are a product of anthropogenic origin. Through experimental studies, Wiederhold and Pevny (2014) found that “regardless of the amount of trampling damage, 99% of all fractures and detachments” that are the result of these natural processes occurred in “random locations on edges” (Wiederhold and Pevny 2014:110). Fractures along the margins of lithic items that are the result of postdepositional processes are typically unpatterned, discontinuous, and occur on multiple surfaces of the artifact (Wiederhold and Pevny 2014:110). Moreover, striations that are irregular or that are perpendicular to a margin with unpatterned edge damage should also be considered
the result of natural formation processes. In contrast, trace microwear that results from anthropogenic modification occurs as patterned, regularly spaced removals along the margin of the tool edge that are continuous, overlapping, and uniform in size (Wiederhold and Pevny 2014:110; Odell 1981a). Moreover, evidence of polish and striations should be most prevalent “along the used edge of a tool or where a tool was held or hafted” and in conjunction with the occurrence of other forms of microwear such as micro-chipping (Wiederhold and Pevny 2014:110). The presence of multiple, co-occurring forms of microwear on a given item are stronger indications that the wear patterns identified are the result of anthropogenesis or anthropogenic origin. In the section that follows, the combination of microwear patterns on artifacts from the Topper Site are examined to interpret the types of activities for which specific tool categories may or may not have been used.

Table 7–45 shows the most common microwear patterns observed on items from the study sample as a proportion of all artifacts examined for each depositional unit. At Topper, the most common microwear signature identified was micro-chipping, occurring on 83% of artifacts from the Pleistocene Sands. Micro-chipping results from cutting, sawing, or scraping activities and can sometimes produce bending or conchoidal micro-flakes. Of the artifacts with micro-chipping, 20 also exhibit polish. However, only two of the artifacts with micro-chipping showed evidence of residue and a single bend break also had striations. The high percentage of artifacts having the co-occurrence of micro-chipping and polish are suggestive of the working of materials that are hard enough to result in the detachment of micro-flakes, and also leave behind aspirates in the form of polish on the artifact surface.

According to Kooymen (2000), worked materials can be categorized into a number of hardness types for micro-chipping analysis. These categories include hard (antler, bone dry
wood), medium hard (fresh hardwood, fresh antler), medium soft (soft woods, dry hides), and soft (meat, soft hides). Harder materials tend to produce micro-flakes that terminate in step or hinge terminations whereas soft materials result in feathered terminations. Polish forms as the result of abrasion or deposition of silica on the artifact’s surface. Movement in soil can produce a generic polish that covers the entirety of the artifact’s surface (Kooyman 2000). Greasy polish is typically associated with animal butchering whereas a bright polish is often associated with plant or wood processing. The image in Figure A37–3 shows micro-chipping along the lateral margin of a utilized flake from the Pleistocene Sands at the Topper Site. The micro-flake removals from this piece have feather terminations. Combined with the polish observed on the lateral margins on this piece, the morphology of the micro-flake removals suggests that this tool was likely used to work medium hard to medium soft materials such as fresh hardwood, fresh antler, soft woods or dry hides.

A total of 33 artifacts exhibit evidence of micro-polish (Table 7–45). These items include six scrapers, 13 utilized flakes, one blade, and 13 bend breaks. Polish occurs on two-thirds of the 50 artifacts examined. Of the items with evidence of polish, 20 artifacts also exhibit micro-chipping, 10 have striae, and seven exhibit residue. The high percentage of artifacts with microwear consisting of polish, micro-chipping, and striae can provide insight into the types of cultural activities that were ongoing at the site. However, such conditions might also inform about the various types of natural processes that can leave behind such trace micro-wear. Photomicrographs showing polish on the lateral margins of a bend break and polish on the lateral margins of a scraper are provided in Figure A37–4. Interestingly, the polish on the bend break takes the form of the greasy variety, whereas the polish on the scraper is bright, resulting in a smooth and glossy, highly reflective surface. These findings suggest that at least two different
types of processes produced polish on artifacts at Topper. Moreover, striations visible on the surface of the scraper at an angle diagonal to the margin of the scraper provide evidence of the direction of item motion. The bright leveled surfaces along the rim of the flake scar margins and absence of such conditions within the concavities are indicative of cultural as opposed to natural abrasive processes.

In comparison with micro-chipping and polishing, a lower percentage of artifacts exhibited striae and residue at Topper. Striations were observed on a total of 11 artifacts from the study sample. Striations were most commonly observed on bend breaks comprising 73% of all artifacts having striations. Two scrapers and a utilized flake were also found to have striations. Most examples of striations took the form of parallel linear marks on the micro-topography of the lithic surface originating near the margin of the artifact and extending some distance to the interior of the lithic item at an angle diagonal to the artifact margin. However, four bend breaks from the Pleistocene Terrace had striae that are not uniform in nature, and appear as parallel lines that intersect other sets of striations on the artifact surface. These traces are characteristic of natural modification. A comparison of the additional microwear patterns on items that exhibit striations shows that polish occurs on two of three artifacts; residue is infrequent, only present on three items; and micro-chipping occurs on four artifacts.

The presence of residue was observed on nine artifacts from the study sample (Table 7–45). Artifact types on which residue was observed were fairly evenly distributed among bend breaks (n=3), utilized flakes (n=5), and scrapers (n=1). Potentially identifiable residues on chipped stone tools can include plant and animal tissues. Figure A37–7 shows unidentified residue along the margin of a scraper from the Pleistocene Sands. In cases where residue is the product of cultural activity, the wear patterns are predominantly oriented linearly and
perpendicular or sub-perpendicular to the artifact edges. The linear orientation is generally indicative of the artifacts movement along the work surface of the objective. By contrast, residue resulting from natural processes should lack evidence of linear features at angles that are perpendicular to the artifact margin. In the case of the residue on the scraper, there is no patterning that indicate that the residue was a byproduct of cultural activity or use. In fact, of all cases where residue was identified, there was little evidence of an identifiable pattern that would suggest that the residue observed was definitively attributed to humans. As such, of all the microwear categories considered for this analysis, residue provided the least evidence of human activity onsite.

The study of potential natural, manufacture, and use processes of chipped stone tools is essential for the determination of human versus natural site formation processes and artifact function. Based on the microwear analysis of a sample of 50 items from the Topper pre Clovis deposits, trace microwear attributed to human agency was identified in the form of micro-chipping, polish, and in lower frequencies, striations. The microwear is most prevalent on items from the Pleistocene Sands. Items recovered from the lower deposits of the Pleistocene Terrace have wear patterns more consistent with natural processes. In terms of tool function, the results of the microwear analysis show that use-wear polishes and micro-chipping were likely the result of working materials that are medium hard to medium soft such as fresh wood, bone and hide. However, it should also be noted that natural processes can also leave evidence of microwear such as residue.

Refit Analysis

A preliminary refit analysis was conducted as an aid to establish the origin of the lithic deposits at Topper, and to evaluate whether or not site integrity has been preserved. Appendix 26
presents the distribution and illustrations of refits identified from the study sample. The refit analysis was designed to locate vertically and horizontally translocated artifacts. Accordingly, lithic items that meet the minimum criteria of cultural artifacts and chipped stone debris and that are spatially clustered with regard to a common surface were considered intact archaeological deposits. Only mapped items (n = 4286) were included in the refit study. One to three minutes were given per item to examine artifact attributes and to evaluate refit potentiality. Refits were identified as encountered in the artifact attribute analysis. As such, the study is not comprehensive, and should therefore be considered preliminary as future examinations may produce additional refits with alternative results. The study therefore is best used to document the presence/absence of refits from the study sample, and by what mechanism, cultural, or natural that produced them, rather than informing about reduction intensity.

A total of 13 refit pairs were identified comprising 24 lithic items. When examined by strata, six refit pairs were identified from the Pleistocene Terrace. These include two natural/pebble refits, three debris refits, and a flake fragment refit. Six refit pairs were also identified from the Pleistocene Sands and include three broken quartz pebble/hammerstone refits, one flake fragment refit, one broken flake refit, and a natural/amorphous debris refit. Two biface fragments were found to refit from the Clovis deposits. Based on the attribute analysis, all but three refit pairs (23.08%) were found to meet the minimum criteria of a cultural chipped stone artifact.

The spatial analysis of all refit pairs found that no two refits were separated horizontally by more than 78cm. The mean horizontal separation between artifact refits was 15.02 cm, while the vertical displacement of refits had a mean separation of 2.33cm. The greatest vertical displacement between refits was 7.5cm for two natural chert pebble fragments. When only the artifact refits with attributes consistent with human agency were considered, no two specimens
were separated along the vertical profile by more than 6.8cm and the overall average displacement decreased to 2.08cm.

Refits at Topper tend to cluster in three “zones” throughout the stratigraphic profile at the site. These zones are depicted in Figure 7–5. The first zone corresponds with the Clovis deposits and includes the two biface fragments that refit. The second zone, highlighted in yellow corresponds with the Pleistocene Sands. This zone has six refits including one natural/amorphous debris fragment that refits to a core. Most refits from the Pleistocene Sands were recovered from the lower Pleistocene Sands subunit and exhibit little evidence of vertical displacement. However, the single refit from the Upper Pleistocene Sands is vertical in orientation, a possible indication for the presence of bioturbation from the Upper Pleistocene Sands. The vertical displacement of this refit, consisting of two broken quartz pebbles, and recovered from unit N244 E142 is 5cm. The third zone where refits are common is from the lower Pleistocene Terrace. Four refits were recovered from this zone and include three debris fragments that refit to chert cores, and a flake fragment that refits to a chert core. These items have attributes of human agency. Two additional refits were identified from this zone and consist of amorphous debris items. These two refits are considered natural in origin. Overall, the results of the refit analysis show that there has been relatively minimal vertical movement of artifacts throughout the Clovis and Lower Pleistocene Sands at Topper and the horizontal displacement of artifacts can be explained as the probable byproduct of the manufacture and discard of chipped stone debris.

**Chapter Summary**

The lithic analysis of the chipped stone assemblage at the Topper Site included four analyses: interpretation free analysis, flake formation analysis, stone tool analysis, and
Figure 7–5
Vertical distribution of artifact refits from preliminary refit analysis from the study sample at Topper. Highlighted sections reflect stratigraphic zones where artifact refits are most prevalent. Shaded circles reflect refits consisting of natural pebbles. Unshaded circles reflect refits that exhibit one or more attributes characteristic of human agency. There is no significant vertical displacement between refits.
microwear analysis. The results of the interpretation free analysis show a significant difference in the distribution of debitage categories when the Clovis and pre Clovis units at the site were compared. The Clovis assemblage predominantly consists of complete flakes, broken flakes, and flake fragments, whereas the pre Clovis assemblage is dominated by debris, amorphous debris and pebbles.

A flake formation analysis was subsequently conducted to determine the lithic reduction technologies selected for the manufacture of chipped stone tools at Topper. For example, although the interpretation free analysis found high densities of debris from the Pleistocene Sands, the flake formation analysis was employed to evaluate whether such debris could be the byproduct of technological reduction strategies not related to biface manufacture. The results of the flake formation analysis found evidence that conchoidal flakes are the dominant flake type present from the Holocene and Clovis deposits. In contrast, conchoidal flakes as well as bend break flakes occur in stratigraphic contexts that predate the Clovis deposits at Topper. The debris items recovered from the Pleistocene Sands lack striking platforms and bulbs of force, and are considered possible byproducts of the manufacture of bend break flakes.

The results of the stone tool analysis demonstrate that bifaces are the most prevalent tool form from the Clovis deposits and correlate with the distribution of large quantities of conchoidal flakes. Bifaces were rare in the Pleistocene Sands and Terrace. In contrast, bend breaks were largely absent in the Clovis deposits, and only occur in significant quantities below these depths. Moreover, the bend break items that exhibit the greatest evidence for cultural modification occur from the Pleistocene Sands and upper deposits of the Pleistocene Terrace. Bend breaks from the Lower Pleistocene Terrace lack many of the technological attributes consistent with human agency. Core and flake tools were recovered from all stratigraphic deposits onsite, although they
were found to occur with greatest frequency from the Clovis and Pleistocene Sands deposits. Whereas bifaces are a good indicator of the technological manufacturing trajectories from the Clovis deposits, the co-occurrence of flake tools, core tools and chopper tools from the Pleistocene Sands present evidence for an alternative cultural toolkit from the underlying deposits. An analysis of production tools shows that hammerstones are prevalent throughout the Clovis deposits, whereas anvil stones and broken quartz pebbles are most abundant from the Pleistocene Sands and Pleistocene Terrace respectively. These findings also demonstrate possible differences in the reductive technologies between the depositional units at the site. The results of the tool modification analysis show a general decrease in the frequency of modified tools with depth. Artifacts from the Clovis and Pleistocene Sands deposits provide greater evidence of modification that conforms to attributes consistent with cultural modification than items from the Pleistocene Terrace. The occurrence of modified bend breaks from the Pleistocene Sands should not be mistaken for the manufacture of these tools. Rather modification should be taken to imply only tool use and maintenance. Although a high quantity of debris was identified from these deposits, potentially resulting from the manufacture of bend break flakes, such debris could also result from natural processes. As such, the distribution of modified bend breaks recovered from the Pleistocene Sands could reflect the expedient use of naturally broken chert debris. The presence of bend breaks with low IM scores from the Lower Pleistocene Terrace deposits implies that these items are less likely to be the result of human agency than are the items with higher IM scores identified from the overlying deposits. The microwear analysis demonstrates the presence of use-wear attributed to human agency on lithic items from the Pleistocene Sands and Upper Terrace. Microwear was identified in the form of micro-chipping, polish, and in lower frequencies, striations. The microwear
identified on the bend break graver spur in Figure A37–1 is indisputable evidence of human modification. However, although this artifact was recovered approximately 30cm into the top of the Pleistocene Terrace, it should be noted that the artifact was recovered well within the footprint of BHT 17 and was vertical in orientation, and as such, the potential exits that its context could have been disturbed as a result of the BHT excavation process. The comparatively low percentage of microwear present on items from the Lower Terrace, combined with greater evidence of microwear attributable to natural processes from these deposits, are both factors used to differentiate the assemblages from each depositional unit at the site. In the following chapter the role of natural processes in the formation of lithic materials from the Pleistocene contexts at the Topper Site are examined.
CHAPTER VIII
EXPERIMENTAL ARCHAEOLOGY: EXPLORING NATURAL WEATHERING PROCESSES AND EVALUATING THEIR ROLE IN THE FORMATION OF LITHIC MATERIALS FROM THE TOPPER SITE

Introduction

Lithic materials are subject to a variety of natural processes that can affect the integrity of stone properties and can therefore influence the degree and speed to which lithic items may fracture or deteriorate over time. As discussed in chapter 6, natural weathering variables such as air temperature, moisture content, and water temperature can significantly alter the internal properties of lithic materials in such a way as to produce detachments that might be mistaken for artifacts of cultural origin. Figure 8–1 presents an example of a chert cobble that exhibits features characteristic of natural formation processes. This cobble was recovered from the Topper Site. The analysis reported herein was conducted to assess whether mechanical weathering agents, acting on a given mass of stone, can result in the detachment of lithic items that resemble artifacts of human agency. To test this proposition, four natural mechanical weathering simulation experiments were carried out on a sample of four unmodified cobbles of Allendale chert. The results were subsequently compared to the attributes identified on a control sample obtained from an off-site location, and to the lithic attributes on bend break flakes recovered from the Pleistocene deposits at Topper. The results of these analyses are presented in Tables 8–1 to 8–7 and in Appendix 39. Data recorded for these experimental procedures include material condition, presence /absence of detachments, detachment morphology, and change in cobble weight per weathering cycle.
Figure 8–1
Chert cobble from the Topper Site (38AL23) that has surficial features characteristic of natural formation processes. A; Features resembling hinge or step terminations. These characteristics form as the result of natural weathering of the cobble exterior and can sometimes be mistaken for removal scars. B; pitted surface resulting from crazing, a thermal alteration phenomena that can occur when water is applied to heated stone.

Cobble Sample 1 Analysis: Freeze/Thaw Simulation

For this analysis, a lithic cobble underwent 25 cycles of freezing and thawing for a total of 50 experimental tests (Tables A39–1 and A39–2). Figure 8–2 illustrates the chert cobble before and after undergoing 25 cycles of the experimental weathering process. Change in cobble weight and detachment frequency data are presented in Table A39–1. Little evidence for change in the mechanical integrity of the lithic cobble was evident over the course of the experiments. Four cracks in the surface of the cobble were identified (Table A39–1). Initial cracks ranged in width from 0.1–.8mm, and the longest crack (1) measured 6mm in length. At the completion of the simulation study, this crack had widened to 1.2mm in width and 8 mm in length, although no evidence for additional fracture was observed. An examination of the origin of initial crack formation shows that cracks tended to form on the surface of the lithic cobble at angles perpendicular to one another. Figure A39–1 shows the change in cobble weight for each freeze/thaw weathering episode. Minor fluctuations in cobble weight occurred throughout the weathering process, with the greatest reductions occurring during freezing cycles. The number also indicates a general decline in cobble weight throughout the experimental procedure (Table A39–1). During freezing cycles, average cobble weights were found to be slightly more than during thawing cycles. A t-test comparing the distribution of weights for each freezing cycle by the weights for each thawing cycle found no statistically significant difference at the .05 level of significance (t value = –0.411664; p value = 0.6824; Table A39–2b).

The freeze/thaw simulation produced no detachments. However, the development of cracks in the surface of the lithic cobble suggest the potential that given enough time under such conditions, detachments could result from repeated freezing and thawing of Allendale chert. The
Figure 8–2
Chert cobble Sample 1 selected for Freeze/Thaw simulation prior to undergoing experimental weathering, and B after undergoing 25 cycles of the experimental weathering process. Note that very little change has occurred to the exterior surface of the cobble over the course of the study. Freezing and thawing alone had limited influence on lithic detachment.
observation of cracks forming at right angles on the surface of the test cobbles is intriguing, and could ultimately lead to the formation and detachment of items that resemble bend break flakes.

**Cobble Sample 2 Analysis: Freeze/Thaw/Soak Simulation**

An analysis was conducted to determine the effects of temperature and moisture on a sample of lithic materials. For this experiment cobble Sample 2 underwent 25 cycles of freezing thawing and soaking for a total of 75 experimental tests. The information is presented in Tables A39–3 to A39–6 for each weathering variable. Cobble Sample 2 is illustrated in Figure 8–3. The initial weight for Cobble Sample 2 was 1.36kg. Morphological attributes of detachments from Cobble Sample 2 are presented in Tables A39–7 to A39–9. Over the course of the experimental procedure the weathering simulation resulted in the detachment of 69 lithic items (totaling 153.2g) from cobble two as the result of the combined soaking, freezing, and thawing process (Tables A39–3 to A39–6). Figure A39–2 presents a series of time lapse photos taken of cobble two as the simulation of weathering cycles progressed. As is evident, the cobble underwent a series of fracture episodes whereby numerous detachments exfoliated from the exterior surface of the cobble. A number of fractures were angular and resulted in detachments that resembled bend break flakes. The development of one such fracture can be seen in Figure 8–5. The formation of fractures and cracks in the cobble exterior surface increased with each subsequent weathering cycle, eventually leading to the production of lithic detachments.

All 69 detachments were examined for specific lithic attributes for the purpose of an Interpretation Free Attribute analysis. Detachments produced during early cycles of the weathering simulation typically resulted in items classified as small cortical debris and cortical pebbles. In contrast, items detached during later cycles tended to exhibit tertiary exterior
Figure 8–3

surfaces, were larger and heavier in size, and contained attribute states identified as amorphous debris.

A technological analysis of the lithic detachments shows that most items are cortical pebbles (Table 8–1; Figure 8–6 top). These items are completely cortical and resemble cortical pebbles as a detachment surface is apparent. The remaining detachments have attributes consistent with amorphous debris (Figure 8–6 bottom) or in rare instances debris (Figure 8–6 middle). Many of the detachments exhibit morphological attributes consistent with flakes, but lack technological attributes such as a striking platform, a bulb of force or compression rings (Figure 8–6 middle). The infrequent occurrence of lithic detachments that were classified as debris implies that the weathering simulations seldom produced items that exhibit compression rings. Table 8–2 presents the mean morphological attributes for each interpretation free category. The items classified as debris are largest, with amorphous debris and pebbles much smaller in size. A One Way Analysis of Variance comparing artifact morphology by interpretation free category shows a statistically significant difference in measures of length and width when detachments classified as debris were compared to items classified as amorphous debris (Table 8–3). However, when measures of detachment thickness and weight were considered, there was no statistical difference between the debris and amorphous debris assemblages.

When the morphology of detachments was further classified by cortex, the items that retain partial but not complete cortex are on average larger than items that are either cortical or tertiary. Interior or tertiary amorphous debris represent the smallest lithic category. A One Way Analysis of Variance comparing the amorphous debris detachment morphology by cortical class shows that the observed differences in size are not statistically significant (Table 8–4, Table A39–3). Cortical pebbles are significantly smaller than amorphous debris or debris.
Figure 8–6
Detachments formed from Cobble Sample 2 subjected to the freeze/thaw soak weathering simulation.
The analysis failed to identify any detachments that could be classified as complete flakes, broken flakes, or flake fragments. However, two detachments display attributes consistent with bend break flakes. These items are presented in Figure 8–9 and are characterized by having two or more 90 degree break angles and interior surfaces, but lack evidence of ripple lines and compression rings. It is important to note that neither of these specimens exhibit evidence of removal or retouch scars that could be readily mistaken for human modification. Moreover, there is no evidence of impact markers that would typically be found on the exterior surfaces of bend breaks resulting from lithic reductive activities.

In addition to the cortical and morphological analysis, all lithic items were examined by the type of weathering variable that preceded its detachment. Table 8–5 shows the number and interpretation free category of detachments by weathering cycle. The soaking cycle predominantly produced items classified as cortical pebbles or cortical/secondary amorphous debris. The freezing cycle mostly produced items classified as cortical pebbles or secondary amorphous debris. The thawing cycle also produced high numbers of cortical pebbles. Most debris and interior tertiary fragments were detached during freezing cycles. To examine the effects of each weathering variable on the properties of lithic materials in greater detail, the soaking, freezing, and thawing cycles were evaluated independently (Tables A39–4 to A39–6). Accordingly, each individual weathering cycle for Cobble Sample 2 is discussed in the following section.

Soaking Cycle

Table A39–4 shows the variation in cobble weight recorded following each 12 hour soaking cycle. Ten lithic items detached from Cobble Sample 2 during soaking cycles. These
Lithic detachments having the morphological characteristics of bend breaks formed as a result of the freeze/thaw/soak weathering simulation Item detached from Cobble Sample 2. This example lacks a lip that often occurs on bend breaks formed by bending and compression flaking.

detachments include cortical pebbles, secondary amorphous debris, and cortical amorphous debris. The frequency of detachments was found to increase as the number of soaking cycles also increased. Consequently, the average weight of the cobble also decreased through time as more detachments were separated from the cobble exterior. The morphology of all lithic detachments was recorded and the results are presented in Tables A39–7 and A39–8. The materials produced from the soaking process were more often smaller but heavier than those produced by other weathering processes. A One Way Analysis of Variance shows that the observed differences in morphology for detachments produced by soaking are not significantly smaller than those produced by way of other weathering processes at the statistical .05 level (Table A39–9). When the morphology of lithic detachments for each soaking cycle was examined by Interpretation Free Category, detachments classified as secondary amorphous debris were found to be the largest. By contrast, detachments classified as cortical chert pebbles were the smallest (Table A39–8). It appears that the detachments that formed early in the experimental procedure have attribute characteristics that are similar to cortical pebbles and small cortical debris. Detachments produced during latter cycles of the experimental soaking procedure tend to produce smaller amounts of cortex on the exterior surface and are larger in size.

Freezing Cycle

The information recorded from the freezing cycle are presented in Table A39–6. A number of interesting patterns were identified from the morphological analysis of the chert cobble throughout the freezing experiment. The results of the analysis indicate that the cobble was typically lighter during freezing cycles than during soaking phases. This is likely the result of water absorption and evaporation and the result of fragmentation and detachment.
Twenty nine lithic detachments were observed from Cobble Sample 2 during the 25 freezing cycles in addition to five items that fragmented post detachment. These detachments include cortical pebbles, secondary amorphous debris, interior amorphous debris, cortical amorphous debris, secondary debris, and interior debris (Table A39–3). The morphological attributes of detachments formed during the freezing procedure are presented in Table A39–7. On average, detachments produced during freezing cycles are larger in size, yet slightly lighter than lithic detachments produced during the soaking cycles. When detachment weights were considered, those produced as a result of the freezing cycle were slightly lighter than those produced as a byproduct of soaking. An examination of the frequency of detachments by weathering condition found that freezing cycles tend to produce greater quantities of detachments per cycle than soaking episodes. Moreover, freezing cycles also tend to produce higher percentages of detachments during the early stages of the weathering experiment first 10 cycles) compared to the frequency of detachments observed during soaking cycles.

**Thawing Cycle**

The data from the thawing cycles for Cobble Sample 2 are presented in Table A39–6. Based on results of the study, the average cobble weights during thawing cycles were lower than were found to occur during either soaking or freezing cycles. In general, the thawing cycles produced higher quantities of lithic detachments than either soaking or freezing cycles. Such detachments were presumably formed as cracks that were formed during the freezing and soaking processes begin to contract during subsequent thawing cycles. The cumulative sum of 25 thawing cycles resulted in a total of 30 lithic detachments from sample cobble two. These detachments include cortical pebbles, cortical amorphous debris, secondary amorphous debris, and secondary debris. A sample of these detachments was subjected to subsequent freezing and
soaking cycles. This procedure resulted in the formation of an additional 10 cortical pebbles that resulted from the fragmentation of the lithic exterior prior to detachment.

All detachments formed during thawing cycles were examined by morphology and the results of analysis are presented in Tables A39–7 and A39–8. The detachments produced during thawing cycles are smaller than those produced during freezing cycles, but are larger than those resulting from soaking cycles. Interestingly, when detachment weights were compared, those produced as a result of the thawing process were considerably lighter than detachments resulting from the soaking or freezing cycles. An examination of the frequency of detachments by weathering condition found that thawing cycles tend to produce greater quantities of detachments per cycle than either freezing or soaking episodes (Table A39–7). In contrast to soaking and freezing simulations, the majority of the lithic detachments produced as a result of the thawing process were found to occur during the last few weathering cycles conducted; most occurring between cycles 17 and 23. No detachments occurred as a result of thawing until the 12th weathering cycle. On the contrary, detachments produced as a result of soaking or freezing were observed as early as the 4th and 5th cycle respectively.

**Cobble Sample 2 Summary**

The experimental weathering procedure demonstrates that the combined effects of air temperature and moisture content on Cobble Sample 2 have a greater influence on the mechanical integrity of lithic materials than the single variable air temperature alone. This discovery is evident by the absence of detachments observed on Cobble Sample 1 which was only subjected to freezing and thawing. Over the course of the weathering experiment, Cobble Sample 2 experienced a total weight loss in detachments of 153.2g for an average of 2.35g per detachment. These results imply that a combination of weathering processes rather than one
single variable are more likely to accelerate the mechanical breakdown and degradation of chert materials over time. Moreover, the detachments produced from the combined weathering variables predominantly exhibit attributes consistent with amorphous debris. As such, these items can be distinguished from conchoidal flakes that result from human lithic manufacture episodes by the absence of a striking platform, bulb of force, and ripples or compression rings on the interior surfaces of the detachments. Interestingly, a small percentage of detachments do exhibit attributes consistent with items classified as debris. These items have features on the interior surface of the detachment that resemble undulations and compression rings. Although items that were classified as amorphous debris and that fit the morphological description of bend breaks were produced from the procedure, no single detachment that was classified as debris was found to fit the technological description of bend or compression initiation flakes.

Results of Cobble Sample 3: Freeze/Thaw/Soak/Warm Simulation

The third weathering simulation examined the effects of water and air temperature on the material integrity of an Allendale chert cobble. The data recorded during this experiment are presented in Tables 8–6, A39–10 to A39–12, and Figures 8–10, and A39–3. Morphological attributes were recorded for Cobble Sample 3 prior to undergoing the simulation experiment. The cobble initially measured 130.5mm in length, 95mm in width and 52mm in thickness. Its initial weight was 0.45kg. Over the course of the experimental procedure the weathering simulation resulted in the detachment of three lithic items from the cobble (Table A39–11 and A39–12). Figure 8–8 presents a time lapse photo taken of this cobble as the simulation of weathering cycles progressed. Compared with the second weathering experiment, Cobble Sample 3 produced a much lower frequency of fracture episodes resulting in only three detachments.
Figure 8–10
Lithic items resembling flakes and flake fragments from the off–site control assemblage. These items lack modification, micro–wear, compression rings and impact markers attributed to applied force consistent with lithic reductive technologies. Specimen at top has differentially weathered exterior surface removal scars.
Moreover, very few changes were observed on the surface of Cobble Sample 3 compared with the cobbles from the two prior experimental procedures. The three detachments from sample Cobble Sample 3 were examined by attribute conditions for the purpose of an Interpretation Free Attribute analysis (Table 8–6). Detached items were classified as tertiary amorphous debris, cortical chert amorphous debris, or cortical chert pebbles. Morphological attributes for each detachment are presented in Table A39–12. The detachments increase in size as the number of weathering cycles also increases. An analysis of the exterior and interior surfaces of these detachments found no evidence for attributes that are consistent with either flake or bend break manufacture.

To examine the effects of each weathering variable on the properties of the lithic cobble in greater detail, the results of the warm soaking, freezing, and thawing cycles were evaluated independently. Table A39–10 shows the cobble weights recorded following each 12 hour warm/soaking cycle. Over the course of the soaking cycles, the weight of the cobble fluctuated. Interestingly, the recorded weight of the cobble actually increased through the first 12 weathering cycles with lower recorded weights from cycles 13–25. This increase in weight is presented in Figure A39–3 which compares the cobble weight per cycle for each weathering condition. No visible change in the material integrity of the cobble was observed over the course of the first ten soaking cycles. Following weathering cycle 11, small cracks were observed along the exterior surface of the cobble. Theses cracks began to widen by the 21st weathering cycle and following the 23rd cycle, additional micro-fractures were observed on the cobble exterior. No detachments were observed as a direct result of the warm soaking procedure. On average, the weight of the cobble was lighter during freezing cycles potentially due to the evaporation of water from the pores on the exterior surface of the item (Table A39–11). Cracks along the cobble
surface began to form during the 9th freezing cycle leading to single detachment separating from the parent material during the 14th freezing cycle. The morphological attributes of this detachment are presented in Table 8–6. The item was classified as interior amorphous debris and was thin relative to its width. The lithic detachment lacked attributes consistent with those that might be expected to form by lithic production technologies.

The thawing cycle data for Cobble Sample 3 are presented in Table A39–12. Cobble weights exhibited greater variance over the course of this weathering cycle than observed during freezing or warm/soaking cycles. Interestingly, no visible cracks were seen to form during thawing cycles. However, two detachments formed during thawing cycle 17 and include one cortical pebble and a secondary amorphous debris fragment. These detachments were both larger than the single detachment formed during freezing cycle 14 but lacked attributes consistent with lithic production technologies (Table 8–6). Based on the results of this analysis, the combined effects of air temperature, moisture content, and moisture temperature on Cobble Sample 3 do not have as great an influence on the mechanical integrity of lithic materials as the weathering variables had on Cobble Sample 2. The best evidence for this conclusion comes from the small number of detachments formed over the course of the weathering simulation for this experiment compared with the number of detachments formed during weathering experiment two. It appears that variation in water temperature does not significantly affect the probability that a lithic detachment will form, and that the combination of air temperature and moisture presence (as seen in Cobble Sample 2) are better indicators for the probability of lithic detachment.

**Results of Cobble Sample 4: Soak/Dry Simulation**

The fourth weathering simulation examined the effects of moisture content on the material integrity of a lithic cobble. For this procedure the lithic cobble was immersed in water
for a period of 12 hours and subsequently left to dry at room temperature for a subsequent 12 hours. The cobble selected for analysis was completely cortical and significantly weathered. A total of 25 cycles were undertaken resulting in no change to the cobble exterior. The initial weight of Cobble Sample 4 was measured at 1.72 kg. Over the course of the weathering cycles, the cobble weight fluctuated from 1.72kg to a maximum of 1.90kg after having been soaked in water. No visible cracks, fractures or detachments were observed on Cobble Sample 4 as a result of the weathering simulation. The results of this experiment show that variation in moisture content alone will bear little influence on the probability that a lithic cobble will undergo modification or as a result of weathering. Rather, a combination of variables including air temperature and moisture content are more likely to result in changes to the mechanical integrity of lithic cobbles subjected to significant weathering episodes.

**Weathering Simulation Summary**

A number of conclusions may be drawn from the four experimental weathering procedures. The results demonstrate conclusively that lithic detachments can occur as a byproduct of multiple weathering conditions. For example, most detachments formed as the result of a combination of changes in air temperature and moisture content. In contrast, lithic detachments did not form as the direct consequence of a single weathering variable acting alone such as in experiment one and four. The outcome of the Cobble Sample 2 analysis corroborates these findings; immersing a cobble in water in between freezing and thawing cycles provides a greater probability that fracture and ultimate detachment will develop. Consequently, deposits that experience the combined effects of cyclic fluctuations in the water table and air temperature are more prone to contain lithic materials that have undergone significant weathering processes. Moreover, as each weathering process continues, the rate at which a lithic cobble fragments is
accelerated and increases exponentially. Lithic detachments that were subsequently exposed to additional cycles of weathering were observed to continue to degrade and disintegrate into smaller pieces. It should be of note that since only a single cobble underwent the experimental procedure, it is possible that these results could be due to chance and therefore future experimental tests and replication are necessary to validate or refute these results. Apart from these limitations the results of this study have important implications for the prospect that the pre-Clovis assemblage at Topper is or is not cultural in origin. The results of this analysis show that many of the lithic detachments formed by weathering could be mistaken for chipped stone debris to the untrained eye. Lithic items that fit the morphological description of conchoidal and bend break flakes were produced over the course of the weathering simulations. However, these items lack specific technological attributes that distinguish them from artifacts of cultural origin. No detached items produced in the study exhibit compression rings, bulbs of force, or striking platforms, indicating that they could not have been produced using lithic production technologies. Alternatively, the lithic detachments that were produced are most similar to items classified as amorphous debris from the interpretation free analysis discussed in chapter 7.

**Control Sample and Comparative Study**

Lithic items that fit the morphological and technological description of conchoidal, compression and bend fracture flakes are present at Topper. However, natural processes can sometimes mimic the attributes of human lithic reduction technologies. Such items are often referred to as geofacts. The results of the weathering experiments demonstrate that the simulation of natural processes under controlled conditions can create lithic detachments that are morphologically similar to cultural artifacts but that lack many of the technological attributes produced by human agency. But what is not known is how well the results of the weathering
experiments actually compare with an “authentic” or actual natural assemblage of items that might be morphologically similar to flakes and bend breaks. The following analysis examined the material and morphological attributes of a “control” assemblage of lithic items that resemble flakes and bend breaks. These items presumably formed under natural conditions and in deposits where diagnostic material culture is absent. The items that comprise the control assemblage are of Fort Payne chert and were recovered in June, 2012 from alluvial clay and colluvial silt loam deposits from Williamson County, Tennessee (approximate latitude N 35.8650, longitude W - 86.7071. Table 8–7 and Tables A39 – 13 to A39 –23 present the attributes examined for the analysis. Examples of these chert items are presented in Figures 8–9 and 8–10. The control sample consists of 70 items. These include 50 specimens preliminarily classified (based on morphology) as bend breaks and 20 preliminarily classified as conchoidal flakes and flake fragments. The results of analysis were compared to the morphological and technological attributes of the Topper flake and bend break assemblages as well as the attributes of the detachments formed from the weathering simulation study (Table 8–8). The descriptive statistics obtained from the attributes of the comparative analysis were used to form the basis of more robust statistical analyses including t–tests and One Way Analysis of Variance (ANOVA). The results of the morphological attribute analysis are presented first. The results of a comparative attribute scoring analysis are presented in Appendix 39.

Bend Break Morphology

Tables 8–8 and A39–14 to A39-21 present the analytic results of the control analysis. The previous section demonstrated that despite the marked differences in the technological attributes of the experimental and Topper assemblages, there is similarity in the morphology of lithic

detachments from these two assemblages. Based on the evaluation of the control assemblage, some of these same patterns are consistent. On average, bend breaks from the control sample are longer and heavier than Topper bend breaks, while widths and thicknesses are essentially identical (Table 8–8, Figures A39–4 and A39–5). Bend breaks from the experimental assemblage are longer, wider and heavier than items from the Topper or control assemblages. This difference could be explained as a result of the small sample size (n=3) of the relatively large bend breaks produced from the experimental assemblage. While the descriptive statistics indicate the occurrence of morphological similarity between the lithic assemblages under scrutiny, additional analyses were undertaken to establish whether the observed differences were statistically significant. The results of a One Way Analysis of Variance show that the observed differences in artifact length and width are actually statistically significant when all three assemblages are compared, while no statistical difference was found for attributes of artifact thickness and weight. The small p values for artifact lengths imply that it is unlikely that the observed differences are due to random sampling.

Table A39–15 lists the p values obtained from a two-way t-test comparison of bend break morphology from the Topper and control samples. Only artifact length and weight are statistically different at the .05 Alpha–level. No evidence was found to suggest that measures of width and thickness represent statistically different populations. When bend breaks from the Topper and experimental assemblages were compared, there is evidence for association in measures of artifact length, thickness and weight but not for artifact width. As a test to examine the statistical relatedness between the control and experimental assemblages, the p values were also obtained for attributes of morphology. The variation present in artifact width for the two samples is statistically significant. By contrast, because the p values for the other variables
(length, thickness, and weight) fell outside of the .05 alpha level, the analysis did not achieve statistical significance.

*Flake Morphology*

The morphological attributes of the flakes from the Topper, control, and experimental assemblages were also examined. Figures A39–7 and A39–8 present a series of bar charts that show the average flake size for each lithic assemblage. When the Topper flake assemblage was compared to the control assemblage, the results indicate strong similarity in size. Flakes from the experimental assemblage are on average, smaller and lighter than flakes from the Topper and control assemblages. To examine these patterns in greater detail, a One Way Analysis of Variance test was conducted comparing the morphological attributes of flakes from each assemblage. This test compared all three lithic assemblages to determine if one or more are statistically different in terms of artifact morphology. The results of this test are presented in Table A39–16 and show that flakes from the Topper, control, and experimental assemblages are not statistically different at the .05 significance level in terms of morphology. The morphology of items that resemble flake detachments from the experimental and control assemblages do not differ significantly from the lithic items classified as flakes from the pre-Clovis deposits at the Topper Site.

While the results of the ANOVA analysis are useful for establishing the degree of similarity between three or more lithic assemblages, a t-test was also employed to directly compare 1) the Topper and control assemblage 2) the Topper and experimental assemblage and 3) the control and experimental assemblages separately (Table A39–17). Table A39–17 presents the p values obtained from a two-way comparison of the metric attributes from each of the flake assemblages. When the Topper and control assemblages were compared the p values for all
variables of flake size fell outside of the 0.05 alpha level implying that the analysis did not achieve statistical significance. The two samples are not statistically different. The same patterns were also found when the Topper and experimental assemblages were compared; that is there is no statistical difference in the morphology of flakes between the two assemblages. However, when the control and experimental flake assemblages were compared, there is a statistically significant difference in the morphology of flake width, thickness and weight at the $p = 0.05$ level, and a statistically significant difference in flake length albeit at the $p = 0.1$ level. As such, there is less than a 10% chance that the two samples are statistically related. These findings suggest that items classified as flakes from the control assemblages share similarity in morphology with flakes from the pre Clovis Topper flake assemblage.

The results of the comparative analysis demonstrate that bend breaks and flakes recovered from the Pleistocene deposits at Topper are morphologically similar to items recovered from an off-site independent control sample that was produced by natural processes. However, the results also indicate that the Topper assemblage presents greater evidence for technological attributes that are consistent with human use than either the control or the experimental assemblages. Given these results, at most the Topper and Control assemblage could have formed under similar conditions that resulted in comparable morphologies, but only the Topper assemblage has been subjected to “technological” processes that could potentially have been the product of anthropogenic behavior. However, it is also important to note that any observed differences in morphology could be the result of variation in raw material type between each sample.
Technological Analysis

Because lithic items that form in nature can also have attributes that appear similar to the attributes visible on cultural flakes, a technological attribute analysis of the lithic items from the control assemblage was undertaken. The results were subsequently compared to the technological attributes found on items classified as bend breaks and flakes from the Topper pre-Clovis and experimental assemblages. For this analysis, each assemblage was evaluated by the number and condition of exterior surface removal scars (Table 8–8). Flakes and bend breaks from both the control assemblage and the experimental assemblage exhibit much fewer exterior surface removal scars than items from the Topper assemblage. Topper flakes exhibit nearly twice as many removal scars as flakes from the control assemblage, whereas flakes from the experimental assemblage average less than one removal scar per lithic item. Of note, when the mean number of cumulative detachment scars on bend breaks were considered for each assemblage, there was found to be little variance.

To test if the observed differences between the group means for the variable “removal scar count” for the flake categories are statistically significant, a one way analysis of variance (ANOVA) calculation was performed (Table A39–18). The p value was used to test the null hypothesis that all group population means are equal versus the alternative that at least one group is not equal. The results of the test provided an extremely low p value of 3.80E–18 indicating that there is a significant difference in terms of removal scar count between the means of the three independent (unrelated) groups. A Brown–Forsyth test was conducted to account for the unequal variance. Based on the results, the p value is still extremely small, p <0.001 and therefore the null hypothesis that all group population means are equal is rejected (Table A39–19).
Next, the lateral margins of lithics from each of the three assemblages were examined for possible retouch. The results of this analysis are presented in Table A39–13 and following Andrefsky’s (2012) Index of Modification, reflect the average number of retouched segments on bend breaks and flakes from each assemblage (designated as Av. R), and the average number of retouched segments for items having at least one retouch scar (IR). No items from the experimental assemblage have evidence for retouch. When the control and Topper assemblages were compared, the Topper Site was found to consist of a much greater percentage of bend breaks and flakes that have high retouch indexes. To determine whether these results were statistically significant, an ANOVA test was performed for each of the bend break and flake artifact categories. The results of these analyses are presented in Tables A 39–20 and A39–21. There is a statistically significant difference between the means of the three independent (unrelated) groups for the flake category. The results for the bend break category are similar although less conclusive. The ANOVA comparing the control, experimental, and Topper assemblages resulted in a p value of .09, indicating that although strong, analysis did not achieve statistical significance at the .05 alpha level. There is therefore a 9% chance of finding such an association in the incidence of bend break retouch among the two samples due to random chance.

Finally, the number of break angles on bend breaks for each of the three assemblages was evaluated to determine if there were any patterns of similarity or difference. Of the three bend breaks identified from the experimental assemblage, each consisted of two identifiable 90 degree break angles. Similar patterns were found on bend breaks from the control assemblage. By contrast, bend breaks from the Topper assemblage were found to have a higher mean break angle per item than either of the other two assemblages sampled. Because these break angles form sharp protrusions that could have been suitable for a number of grooving, drilling, or gouging
activities, they are considered for the purpose of this study as a technological attribute rather than a morphological attribute. Combined with the higher incidence of retouch and removal scars found on bend breaks from the Topper sample, break angles are a third technological attribute that distinguish the Topper sample from the control and experimental assemblages.

The results of the comparative analysis demonstrate that bend breaks and flakes recovered from the Pleistocene deposits at Topper are morphologically similar to items recovered from an off-site independent control sample that was produced by natural processes. However, the results also indicate that the Topper assemblage presents greater evidence for technological attributes that are consistent with human production than either the control or the experimental assemblages. These results support the conclusion that at most the Topper and Control assemblage could have formed under similar conditions that resulted in comparable morphologies, but only the Topper assemblage has been subjected to “technological” processes that could potentially have been the product of anthropogenic behavior.
CHAPTER IX
CORTICAL ANALYSIS

All cortical pebbles, quartz pebbles, and lithic debitage recovered from the 1/8 inch screen bags from the sampled units at Topper were examined by quantity and weight. The primary data for these analyses are presented in Appendix 41. Each of these material byproducts are considered variables that can inform about cultural or natural site formation processes that were active at the site in the past. For example, the presence of cortex, cortical debris, and cortical pebbles indicate either: 1) the byproduct of human chipped stone tool production, or 2) produced from mechanical weathering processes that degrade lithic materials over time (Figure 9–1). Quartz indicate the input by fluvial processes from a river or stream. Figure 9–2 illustrates the stratigraphic distribution of quartz pebbles from the Pleistocene Sands of 2m x 2m unit N246 E138 at Topper. Where a high occurrence of debitage is found in association with quartz, there is a greater likelihood that the flakes were either redeposited or actually formed by the contact between quartz and brittle solids such as chert. Finally, the amount and distribution of debitage onsite can be used as an indicator of the intensity of onsite lithic reduction. The debitage category is further classified by condition (river stained cortex, thermal alteration) and can inform about changing patterns of tool stone availability or preference through time. Appendix 41 presents the distribution of cortex and quartz for each level and unit at Topper across the study sample.

In this section, the results of the cortical analysis for three stratigraphic deposits at Topper are presented: the Clovis, Pleistocene Sands, and Pleistocene Terrace. Three excavations were considered for this analysis and include the 2010–2011 4m x 4m block excavation; the 2002–2012 5x9 block, consisting of the southern and northern terrace excavations; and the 2000
Figure 9–1

Photo showing quartz pebble lenses from the Pleistocene Sands of North profile wall of unit N246 E138
4m x 8m block (Figures 9–3 and 9–4). All materials examined for this analysis derive from the screen and do not include mapped items.

It is important to note that some 1m x 1m units from the Pleistocene Sands have been excavated to greater depths than other areas that may have originally been a part of the same 2m x 2m unit. Once the terrace surface was reached, some units were selected for continued excavation into the Pleistocene Terrace itself, while excavation in other units was halted at the Pleistocene Terrace surface. The 2000 4m x 8m block excavation was only excavated to the Pleistocene Terrace surface and as such, only includes materials from the Holocene and Pleistocene Sands deposits. One 2m x 2m unit from this block was analyzed and is presented in Table A41–1. The 2010–2011 4m x 4m block only includes materials from the Pleistocene Sands. The results of the cortical analysis for these units are presented in Table A41–2.

A total of 14 1m x 1m units from the 5m x 9m block excavation were excavated from the Holocene deposits to the base of the Pleistocene Terrace. The results of the cortical analysis for these 1m x 1m units are presented in Tables A41–3 to A39–17. An additional 21 1m x 1m units were excavated from the Holocene deposits to the base of the Pleistocene Sands, the results of which are presented in Tables A41–18 to A41–24.

**Distribution of cortical, quartz, and flake debris**

**Cortical Pebbles**

Table 9–1 presents the distribution in weight (g) of all lithic materials by category recovered from the 1/8 inch screened deposits at Topper. Over six hundred kilograms of lithic materials were recovered from these deposits, of which 185,632.67g were identified as cortical pebbles. Overall, cortical pebbles make up the lowest percentage of lithic material (in weight) from the Clovis deposits. Items classified as quartz and flakes from the Clovis deposits weigh

</table>
significantly more than cortical pebbles. Compared to the cumulative amount of lithic items recovered onsite, the items classified as Clovis cortical pebbles account for very little of the total sum of all lithic categories recovered from the site. Given the observed sum weights for each material type by stratum, it is possible to determine how much each category varies from the expected weight. The variation between the observed and expected values can be calculated as a percentage of deviation. Table 9–1 also shows the expected percentage deviation in weight for each lithic category by stratigraphic deposit. Accordingly, Clovis cortical pebbles comprise a lower proportion of the cumulative Clovis bulk weight assemblage compared with flake weight.

Figures A41–1 to A41–15 present the distribution of all lithic materials by category for each stratigraphic deposit at Topper. There is a general increase in the amount of cortical materials by weight through time; beginning with the initial Clovis period, and peaking at the elevation depth of 98.20m. This pattern is followed by a decreasing trend in cortical weight extending into the subsequent Early Archaic deposits (Figures A41–1 to A41–15). The greatest abundance of cortical pebbles from the Paleoindian and Archaic deposits co-occur with the greatest abundance of chipped stone artifacts and debris.

A total of 108,113.75g grams of cortical pebbles were recovered from the 1/8 inch screened Pleistocene Sands deposits (Table 9–1). There is no significant change in the percentage of cortical pebbles when the deposits from the Pleistocene Sands are compared with the proportion of items from the Clovis deposits. Most cortical pebbles by weight was recovered from the lower 40cm of the Pleistocene Sands and at the contact with the Pleistocene Terrace (Figures A41–1 to A41–15). These levels range between 97.15 and 97.55m. There is a decrease in total cortical pebble weight throughout the Upper Pleistocene Sands. These levels range in
depth from 97.65m to 97.95m. The cortical pebbles from the Pleistocene Sands deposits are also not sorted by weight (e.g. with a continual increase or decrease in weight through the profile).

These results of the size grade analysis have implications for the potential for postdepositional transformation of the archaeological deposits at the site. If materials were being sorted by size and weight then the expectation favors downward migration of the smaller lighter pieces toward the base of a given deposit. If such processes are occurring, then there should also be a visible trend in artifact weight through the depositional profile. At Topper this is not the case. The heavier cortical materials occur first within the Clovis deposits, subsequently decrease in weight throughout the upper Pleistocene Sands, and finally increase in weight again at the base of the Pleistocene Sands. There is little evidence for significant size sorting by weight of lighter cortical pieces downward through the profile at Topper, and there is also no decreasing trend in cortical weight through the depositional profile. These finds imply that bioturbation is not responsible for significantly altering the stratigraphic contexts and distribution of cortical pebbles throughout the Lower Pleistocene Sands at the site.

A total of 184,280.36 g of lithic materials were recovered from the Pleistocene Terrace. Approximately 40% of the screened materials from the unit were identified as cortical pebbles. A higher percentage of cortical pebbles were identified from these deposits than from the Clovis or Pleistocene Sands (Table 9–1). Moreover, cortical pebbles from the Pleistocene Terrace make up a higher than expected proportion of the cumulative bulk weight assemblage compared with quartz or flake weight (Table 9–1). This implies that, given the total weight of lithic material from the Pleistocene Terrace, the observed cortical weight differs by 31.9% from the expected weight by volume. However, when examined by depth, the amount of cortex by level remains relatively low throughout much of the Upper Pleistocene Terrace levels. Cortical weights for
these levels average less than 200g/level between elevations 97.10m and 96.10m (Appendix 41). By contrast, the lower 20cm of excavated Pleistocene Terrace deposits average more than 1000g of cortical pebbles by weight. Below the 96.19m elevation, there is an apparent incremental increase in the amount of cortex by weight extending to the base of the Pleistocene Terrace excavation at 95.35m (Appendix 41). The increase in cortical materials at the base of the Pleistocene Terrace excavation correlates with an increase in flake and quartz weights from these deposits, and could reflect the deterioration by weathering of larger chert boulders within the sediment matrix at these levels.

Quartz Pebbles

Over 400 kilograms of quartz pebbles were recovered from the screen bags from excavation sample (Table 9–1). Clovis quartz comprises a higher percentage of the cumulative total of lithic material from the unit than the percentage of cortical materials. The vertical distribution of quartz is presented in Figures A41–1 to A41–15. The distribution of quartz pebbles decreases in weight through time. Quartz pebbles are most abundant from the Upper Pleistocene Sands (97.65m) and decrease in abundance through the Early Archaic deposits 98.30m. This pattern could reflect a change in the channel regime of the Savannah River from a braided system to that of a meandering system over the course of the Late Pleistocene. This adjustment would have resulted in the lowering of quartz deposition at the site through time.

When classified by type, quartz pebbles makeup the greatest percentage of lithic materials from the screen bags from Pleistocene Sands (Table 9–1). Quartz from the Pleistocene Sands comprise 70% of all lithic items recovered from the screen from this depositional unit. There is a significant increase in the abundance of quartz from the Pleistocene Sands compared to the Clovis deposits. The results of a two sample t-test comparing the percentage of pebbles
from each deposit shows that the two assemblages are statistically different (T–statistic = 54.61; 
\( p =< 0.00001 \)) (Table 9–2).

The stratigraphic position of quartz pebbles from the Pleistocene Sands is illustrated in 
Figure A41–18. These pebbles presumably resulted from periodic flooding episodes of the 
Savannah River, sheet wash, or chute channels that drained into the river prior to 15,000 cal yr 
B.P. The highest concentrations of pebbles occur in levels between 97.40m and 97.65m, 
approximately 40–50cm cm above the Pleistocene Terrace surface (Appendix 41).

King (2012) conducted a correlation analysis of these deposits in 2009 to determine if 
there was a relationship between lithic debitage and the co-occurrence of quartz pebbles from a 
sample of units from the 5x9 block excavation. The results of her analysis showed a direct 
association between items identified as lithic debitage and the distribution of quartz pebbles, 
suggesting that non-cultural and potential cultural materials were likely deposited at the same 
time. The present study largely corroborates King’s findings with regard to the distribution of 
quartz pebbles. That is, higher concentrations of quartz deposits are found within the Pleistocene 
Sands. Although there is an incremental increase in the distribution of quartz pebbles by depth 
throughout the Upper Pleistocene Sands, below 97.50m the amount by weight of quartz pebbles 
actually decreases each 5cm level until reaching the Pleistocene Terrace surface.

As mentioned above, the greatest abundance of quartz pebbles occur between 97.40m and 
97.65m (Figure 9–5). Interestingly, and contrary to King’s findings, the distribution of flakes 
does not correlate precisely with this pattern. There is a disproportionate increase in the amount 
of flakes by weight from the Pleistocene Terrace surface extending to a depth of 97.35m (Figure 
9–5). Below the Clovis deposits, the amount of flakes by weight decrease, with a subsequent 
increase between 97.35 and 97.00m As such, the highest concentrations of quartz deposits do

not rest on the Pleistocene Terrace surface, the location of the highest abundance of flakes from the deposit. These patterns are best illustrated in Figure 9–5 which shows that the level of greatest flake weight (97.25–97.15m) and the level of greatest quartz weight (97.50–97.40m) are offset by 25cm.

These results imply that flakes could have been present within the lower 25cm of the Pleistocene Sands prior to the onset of fluvial events that resulted in the deposition of the greatest abundance of quartz pebbles. Thus the high influx of quartz pebbles between elevations 97.50–97.40m could have disturbed, removed, or dislocated an existing assemblage of flakes. An alternative interpretation is that flakes from the Clovis levels have filtered through the quartz deposits of the Upper Pleistocene Sands and have accumulated at the base of the Pleistocene Sands. In this latter case, only flakes of small size grades should be present within these lower deposits.

When classified by type, quartz pebbles were found to make up 57% of the lithic materials by weight from the Pleistocene Terrace and 27% of all quartz identified from the site (Table 9–1) In total 105,459.66g of quartz pebbles were recovered from Pleistocene Terrace deposits; The quartz deposits from the Pleistocene Terrace were presumably deposited by low energy overbank flood deposits from the adjacent Savannah River. Unlike the dense quartz lenses from the Upper Pleistocene Sands, there is little evidence for high intensity flooding episodes from the deposits of the Pleistocene Terrace.

There are no abrupt spikes in the distribution of quartz pebbles within the Upper and Middle Pleistocene Terrace deposits. Rather, the distribution of quartz by level varies little between elevations 97.10–96.10m (Figures A41–3 to A41–7). By contrast, an incremental increase in the abundance of quartz by level occurs beginning at elevation 96.10m and extending
to the base of the Pleistocene Terrace profile at 95.35m. Levels from the Lower Pleistocene Terrace average greater than 1,500g of quartz per level (Tables A41–3 to A41–24). These deposits include quartz pebble sizes that are larger than items from the overlying deposits and form the basis of a fining up sequence that characterizes the geomorphological composition of the Pleistocene Terrace structure (Harris 2010).

Flakes and Debitage

Over 26 kg of flake debitage were recovered from the excavation sample (Table 9–1). Of all lithic categories examined, flakes were the most abundant and heaviest category from the Clovis deposits, accounting for more than 5,000g of individual flakes and flake fragments. In most cases, flake counts range from 50–100 per 1m x 1m unit for the basal levels of the Clovis deposits. By contrast, levels that correspond with the “peak” of the Clovis occupation typically have as many as 500 flakes per level.

A total of 15,372.50g of flakes were identified from the screen bags from the Pleistocene Sands. This includes a total of 42,484 flakes and debitage. These flakes comprise the least abundant material type by weight from the depositional unit. However, when the cumulative distribution of flakes was examined across all depositional units from the site, nearly 60% of all flakes by weight derive from the Pleistocene Sands. These percentages demonstrate the dense nature of the lithic materials recovered from the Pleistocene Sands. When the observed versus expected percentage deviation in flake weight for the Pleistocene Sands was considered, fewer flakes by weight were observed than the statistically expected outcome.

A total of 5,227.8g of flakes were identified from the 1/8 inch screen materials from the Pleistocene Terrace (Table 9–1). This number represents approximately 20% of all flakes identified from the research sample. As was found for the Pleistocene Sands, flakes also
represent the least abundant lithic type from the Pleistocene Terrace in terms of weight, comprising less than 4% of all materials identified. An analysis of the Pleistocene Terrace deposits by flake count resulted in the identification of 15,952 flakes. This number accounts for approximately 23% of all flakes identified from the 1/8 inch screen sample at the site.

A comparison of the cumulative flake totals for each stratum shows a number of intriguing patterns. For example, nearly four times as many flakes were recovered from the Pleistocene Sands than from the overlying Clovis deposits (Table 9–1). When standardized by volume, the Clovis levels consist of relatively high flake totals per level, whereas the Pleistocene Sands exhibit more moderate flake counts distributed over a greater number of excavated levels (Figure 9–6). On average, more than 400 flakes were recovered per level from the 1/8 inch screened Clovis deposits. Flake counts decrease with depth beneath these deposits to an elevation of 97.85m. Flakes recovered from the Upper Pleistocene Sands are often fragmented, and frequently lack attributes associated with biface manufacture. However, there is a subsequent increase in flake counts throughout the lower Pleistocene Sands beginning at elevation 97.60m and extending to the contact with the Pleistocene Terrace surface between 97.15m and 97.00m. Compared with the density of flakes from the overlying Holocene and Pleistocene Sands, the density of flakes from the Pleistocene Terrace tends to be much lower. Flakes from the Pleistocene Terrace rarely average greater than twenty items per level (Figure 9–6), whereas deposits from the Pleistocene Sands were frequently found to average more than 100 flakes per level. It appears that the majority of flakes occur within three distinct zones of the Pleistocene Terrace. Zone one ranges from the Pleistocene Terrace surface to elevation 96.90m. A middle zone ranges in depth from 96.25m–95.90m. Finally, a third and deeper zone consists of a cluster of chert flakes that range in depth from 95.50m–95.30m (Figure 9–6). It should be noted that the
Average flake count by level for all flakes and debitage recovered from the Holocene and Pleistocene Sands. Due to the depth of the Pleistocene Terrace excavations, the vertical scale is compressed on the right hand side of the figure.

Figure 9–6
discrete patterns visible in the distribution of flakes throughout the Pleistocene Terrace should not alone be considered as evidence of human occupation, as postdepositional processes could also account for these patterns.

To determine if a correlation exists in the vertical distribution of flakes and other lithic categories by stratum, a Pearson Correlation coefficient analysis was conducted. All flakes from the Clovis contexts were compared against the distribution of cortical and quartz pebbles (Figure 9–7). The results of the Pearson correlation test show a negative correlation between the distribution of the flake and quartz assemblages. However, a weak positive association is indicated by a value of .4340 when the Clovis flake assemblage was compared to the distribution of cortical pebbles. These patterns show that there is no substantial relationship between the distribution of flakes and other lithic categories from the deposit, and that the distributions are independent.

Next, all flakes from the Pleistocene Sands were compared against the distribution of cortical and quartz pebbles (Figure 9–8). There is a weak positive correlation in the distribution of flakes relative to quartz pebbles (r = 0.3573), and a weak positive correlation in the distribution of flakes relative to cortical pebbles from the Pleistocene Sands (r = 0.3535). These results differ in some respects from the correlation analysis conducted for the Clovis deposits, but are similar in other aspects. For example, whereas there is a stronger correlation between flakes and quartz pebbles from the Pleistocene Sands (r = 0.3537, p =0.003) compared with the Clovis deposits (r = 0.1423, p=0.0001), both stratigraphic deposits exhibit similar weakly positive correlations when the change in distribution of flakes was compared to cortical pebbles. It appears that the association between flakes and quartz is stronger in the Upper Pleistocene

Sands than it is in the Clovis levels whereas the relationship between flakes and cortical pebble/material remains the same for both depositional units.

Finally, a Pearson Correlation coefficient was conducted to test for the degree of similarity between the flake, cortical pebbles and quartz pebble assemblages from the Pleistocene Terrace (Figure 9–9). There is a moderate positive correlation (r =0.7080, p=0.0003) when the distribution of flakes by weight was compared to the vertical distribution of quartz by weight. Similarly, when the distribution of flakes was compared to the vertical distribution of cortical materials throughout the Pleistocene Terrace, the results also found a moderate positive correlation (r = 0.6177, p=<0.0001). It appears that the distribution of flakes from the Pleistocene Terrace, as a measure of weight, correlate with both cortical and quartz pebble materials.

The debitage categories for each stratum were further examined with regard to condition (Table 9–3). For this analysis debitage recovered from the 1/8 inch screen was observed noting river stained cortex and thermal alteration (Table 9–3). A total of 1,054 flakes or flake fragments that exhibit evidence of river staining or river stained cortex on the flake exterior was identified from the Clovis levels. This number reflects approximately 9% of all flakes identified from the Clovis 1/8 inch screened deposits. In terms of morphology, the flakes that exhibit river stained cortex from the Clovis deposits tend to be larger than flakes from corresponding levels that lack river stained cortex. The presence of river stained cortex on Clovis chert flakes suggests that Clovis peoples were extracting cobbles from the nearby Savannah River, exposed as the result of the river down-cutting through the deposits containing the high quality tool-stone. At Topper, the frequency of flakes having river stained cortex increase in abundance during the Early and Middle Paleoindian period, with a subsequent decline observed for the terminal Pleistocene.
Results of Pearson's Correlation Test. A; positive correlation for flake weights by quartz pebble weights from Pleistocene Terrace (p < .00001). B; positive correlation for flake weights by cortical pebble weights from Pleistocene Terrace (p < .00001).
Figure 9–10). Such flakes then decrease in abundance throughout the Early and Middle Archaic period at Topper.

When the flakes from the Pleistocene Sands were examined, there is a significant decrease in the amount of river–stained cortex in the Pleistocene Sands compared with the overlying Clovis deposits. In total, only 46 flakes were found to display evidence of river stained cortex from the Pleistocene Sands. This value reflects only 4.3% of all river stained cortex chert identified in the study compared with nearly 96% of the population identified from the Clovis levels. River stained cortex from the Pleistocene Sands comprises .065% of all flakes identified from the 1/8 inch size grade screen mesh.

When thermally altered flakes were considered, the analysis identified 1,291 flakes from the Clovis deposits. While Clovis is not typically associated with the heat treatment of tool-stone, the presence of thermally altered lithics from these deposits could be explained as the result of bioturbation or downward drift of small flakes from the overlying Archaic deposits. A comparison of the morphology of the thermally altered flakes from these deposits found that most tend to be smaller than flakes that lack thermal alteration. Thermal alteration could also have resulted if detached items were discarded and subsequently burned with refuse. Compared with the lower deposits, more flakes were classified as thermally altered or as river stained cortex from the Clovis deposits than from any other stratum examined onsite.

A total of 582 flakes display evidence of thermal alteration from the Pleistocene Sands. This figure makes up approximately 1.3% of all flakes identified from the Pleistocene Sands and is less than the percentage of thermally altered flakes identified from the Clovis deposits (11%). When the distribution of thermally altered flakes was examined by depth, there is a decreasing trend in the average number of flakes per level below the Clovis deposits. This trend begins at
Figure 9–10
Distribution of river stained cortex by stratum for units N242 E130, N242 E140, and N246 E140. There is an abrupt decrease in the number of flakes that exhibit river stained cortex below the Clovis contexts at Topper.
the base of the Holocene colluvium and extends to a depth of 97.50m, well within the Pleistocene Sands (Figure A41–23). Thermally altered flake counts decrease in frequency between 97.50m and 97.25m. Interestingly, this is the region of greatest quartz influx. This decreasing pattern is an indication that thermally altered lithic items from the Holocene deposits could have been subjected to post depositional processes resulting in vertical dispersion and downward migration through the stratigraphic profile from the Clovis deposits and into the Upper Pleistocene Sands.

Below the Upper Pleistocene Sands, a second spike in the number of thermally altered flakes was identified at the base of the Pleistocene Sands and extends into the Upper portion of the Pleistocene Terrace. This spike is evident in Figure 9–11 between elevations 97.15m and 97.00m in the diagram to the right. It is possible that this deeper distribution of flakes could have formed as a byproduct of the nature of the sediments themselves. Accordingly, small flakes migrating downward through the loose Pleistocene-aged sands could have accumulated on the Pleistocene Terrace surface, thus creating what appears to be a lithic deposit or surface than could falsely be interpreted as cultural. These patterns alone do not confirm or reject the hypothesis that the lithics found within pre Clovis aged sediment were the result of human manufacturing processes, only that two distinct lithic concentrations of thermally altered flakes are present within the stratigraphic profile of the Pleistocene Sands at the site. The discovery of thermally altered flakes within the Pleistocene Sands is interesting given that many lithic items from the deposit have undergone significant weathering. It appears that at least a portion of flakes from the unit may have undergone differential rates of weathering than others (allowing some flakes to retain evidence of thermal alteration).
Figure 9–11
Average number of river–stained and thermally altered flakes by level at the Topper Site (38AL23). Dark red shaded area at right indicates levels with highest average quartz content.
A total of 541 thermally altered flakes were identified from the Pleistocene Terrace. This figure comprises 22.4% of all thermally altered flakes from the study sample. The vertical distribution of thermally altered flakes show a strong positive correlation with the distribution of the entire Pleistocene Terrace flake assemblage as a whole (Figures 9–6, 9–11). The Pearson Correlation test resulted in an r value of 0.7402, and indicates that a linear relationship exists between the two flake assemblages. Therefore based on the vertical distribution, it appears that there are three zones or concentrations of thermally altered flakes within the Pleistocene Terrace formation, and that these concentrations correlate with the spatial locations of the three zones identified for the entire flake assemblage as described above.

Figure 9–9 presents the average number of river–stained and thermally altered flakes by level at Topper. There is a rapid drop in the percentage of river stained cortex flakes per level beginning at the base of the Holocene colluvium at 97.80m. The decline in flake count is far greater and more precipitous than observed for the thermally altered flake category. Moreover, there is no evidence for a secondary spike in the distribution of river stained cortex flakes at the base of the Pleistocene Sands similar to that found for the thermally altered flake category. Moreover, not a single lithic item from the Pleistocene Terrace exhibited river stained cortex on the exterior surface. These discoveries have a number of potential implications regarding site integrity. The findings imply that either: 1), very few river stained cortex flakes are migrating downward through the stratigraphic profile at Topper, 2), river stained chert was not available for exploitation prior to the Clovis occupation at the site, 3), river stained cortex flakes are migrating through the stratigraphic profile in higher than observed frequencies, yet many examples have failed identification as they have undergone severe weathering resulting in leached exterior surfaces, or 4), river stained cortex flakes have weathered to unrecognizability.
in the Pleistocene Sands. If weathering processes had obscured the presence of river staining on chert flakes from the Pleistocene Sands as described in examples three and four above, then it follows that the same processes should have also led to the weathering of the thermally altered flakes, thus obscuring their presence as well. The results suggest that this is not the case. The thermally altered flakes occur in far greater percentages from the Pleistocene Sands than examples of river stained cortex. Furthermore there is no confirmation that weathering has been sufficient enough to remove evidence of thermal alteration on flakes, to obscure an unknown percentage of the thermally altered flakes from the Pleistocene assemblage. Given these patterns, it is more probable that either very few river stained cortex flakes are migrating downward through the stratigraphic profile at Topper, or the relative absence of river stained cortex on flakes from the Pleistocene Sands reflects an absence of exposed tool–stone from the Savannah River prior to 15,000 B.P. The absence of river-stained chert from the Pleistocene Terrace in deposits where upland cortex and thermally altered flakes are present support the proposition that river stained chert was not exposed during the period of deposition of material that became the Pleistocene Terrace following incision, and that postdepositional processes resulting in the vertical movement of lithic items have not affected the stratigraphic integrity of the lithic assemblage contained within the Pleistocene Terrace at Topper.

**Chapter Summary**

This analysis demonstrates that cortical materials are most abundant from three strata on the alluvial terrace at the Topper Site. These strata include the Clovis deposits, the Lower Pleistocene Sands, and the Lower Pleistocene Terrace. The Clovis and Lower Pleistocene Sands correlate with the highest concentrations of 1/8 inch flake debris and flake debris by weight, and could reflect two discrete cultural occupations. The co-occurrence of these two lithic categories
could reflect initial cobble testing or the decortication of large cobbles. Given the similar patterns in percentage of cortical weight from the Clovis and Lower Pleistocene Sands, the occurrence of cortical pebbles from both deposits is likely a product of similar formation processes. In this case, the majority of cortical pebbles likely relates to lithic reductive processes; Clovis cortex produced during the decortication process, and pre Clovis cortical pebbles and debris produced during bipolar reduction.

Quartz pebbles occur in the lowest percentages from the Clovis deposits and in the Upper Pleistocene Terrace. Such pebbles occur with in greater percentages from the Upper Pleistocene Sands and from the Lower Pleistocene Terrace. These quartz lenses have been interpreted as chute channels resulting from fluvial events prior to 15,000 cal yr B.P. (Goodyear personal communication 2014; Leigh 2006, 2008). Quartz occurs in moderate amounts throughout much of the Pleistocene Terrace, increasing substantially in weight per level at the base of the excavation.

Chert flakes occur in high quantities in the Clovis deposits and to a lesser extent at the base of the Pleistocene Sands. These flakes are sparsely distributed throughout the Pleistocene Terrace. Flakes from the terrace are concentrated in three zones which also correlate with the distribution of thermally altered flakes. Thermally altered flakes from all deposits at Topper could reflect intentional human alteration or could represent old surfaces where occasional burning occurred. Although thermally altered flakes are present throughout the stratigraphic profile at Topper, the presence of river stained cortex flakes is restricted to the Holocene and Clovis deposits and to the Upper Pleistocene Sands

Based on the results of the cortical analysis, two cultural occupations were tentatively identified below the Holocene deposits at Topper. These cultural occupations include a Clovis
component identified by high concentrations of flakes between elevation 98.10–97.85m and a second, deeper pre Clovis cultural component demonstrated by elevated flake counts associated with lower levels of quartz in the Lower Pleistocene Sands between elevations 97.25m–97.00m.
CHAPTER X

RESULTS OF ANALYSIS: MASS AND SIZE GRADE ANALYSIS

All lithic materials recovered from each 5cm level from the Holocene, Clovis, Pleistocene Sands, and Pleistocene Terrace screen and artifact bags at Topper underwent mass and size grade analysis. This process began by sorting all screen materials from (screen and artifact bags) from each level by category. Lithic materials were then classified as flakes (complete or fragmentary), cortical chert debris, or quartz pebbles. Each lithic category from every level was subsequently sorted by total weight according to 5 screen sizes. For this step, the flakes, cortical pebbles, and quartz pebbles were independently passed through a series of nested U.S.A. Standard Testing Sieves, using five screen sizes: 2.5in, 1in, ½ in, ¼ in, and 1/8 in (Appendix 41–44).

Although mass and size grade analysis have traditionally been used to differentiate between separate stages of a lithic reductive cycle in the manufacture of chipped stone tools, the procedure is also beneficial for evaluating issues relating to site formation and disturbance such as bioturbation, sediment consolidation, or fluvial transport, among others. For the purpose of this study, mass and size grade analysis was conducted as a means to present and compare the vertical distribution of flakes, quartz pebbles, and cortical pebbles throughout the complete stratigraphic profile at Topper.

First, the cumulative size grade of flakes, quartz pebbles, and cortical pebbles was assessed by depth. The goal of the analysis was to determine whether or not any variation exists in artifact size by lithic category throughout the stratigraphic profile at the site, and if such differences could be attributed to postdepositional site formation processes.
For the flake analysis, three separate Pearson’s correlation procedures were carried out. These procedures examined 1) level flake weight by depth, 2) the percentage of flake weight by size grade, and 3, the linear relationship of flake size grade by depth. If an assemblage has not been affected by natural processes, then there should be no correlation in flake size with vertical depth and flakes should not be well sorted. By contrast, a strong positive relationship in flake size with vertical depth implies that the assemblage contents may have been subjected to disturbance, thus compromising site integrity and the contexts of any archaeological assemblages. The independent cortical analysis was conducted to determine the degree to which mechanical weathering processes have occurred onsite whereas the quartz pebble analysis was employed to assess the extent to which fluvial processes may have led to site disturbance.

Next, the cumulative mass and size of each lithic category was compared. For this procedure, the distribution of flakes was compared to the mass and size of cortical and quartz pebbles throughout the vertical profile at the site. A positive correlation in total flake weight with total quartz weight would imply that the extant assemblage may have been disturbed, reworked, or size sorted as quartz pebbles entered by fluvial activity. A negative correlation indicates a negative association between the flake and quartz deposits and would imply that fluvial processes had little effect on the integrity of the flake assemblage.

Cortex can either form as the byproduct of lithic reduction activities or from the deterioration and weathering of lithic materials over time. An absence of a correlation in the distribution of cortical pebbles and flake weight would provide strong evidence that the cortical deposits likely formed by natural weathering episodes, and therefore that the extant distribution should not be considered associated with the production of the flake debris. Although a positive correlation in total cortical weight and total flake weight by level could reflect a direct
association between the amount of tool manufacture debris and the material byproducts of lithic reduction, other factors could also result in these patterns. For example, a positive correlation might imply that the existing deposits have undergone size sorting by weight, or that higher concentrations of cortical pebbles indicate the greater likelihood that items that look like artifacts might be present. To differentiate between these possibilities, the cortical and flake materials were examined relative to the distribution of quartz pebbles. If the flake and cortical pebble assemblages have undergone size sorting by weight, and such patterns are due to natural processes, then the agents responsible for such size sorting should also result in the size sorting of quartz pebbles. Therefore, well-sorted materials resulting from natural processes are identified by a strong positive correlation in the combined total weight of flakes, cortical pebbles and quartz pebbles. By contrast, where there is only a correlation in the weight of flakes and cortical pebbles, the distribution is interpreted as a stratigraphically intact assemblage of lithic debris resulting from episodes of lithic tool production. Quartz pebbles can be employed as a proxy to differentiate between site formation processes and episodes of tool production. The sections below provide the results of the mass and size grade analysis for the flake, quartz pebble, and cortical assemblages at Topper.

**Mass and Size Grade Analysis: Distribution of Flakes**

The distribution of flakes for each size grade at Topper is presented in Appendix 42. Far more flakes occur within the Clovis deposits at the site. Average flake weights for the Clovis deposits range from 60g to 90g per level. Below the Clovis horizon, the abundance of flakes by size grade exhibits a sharp decline in weight. For example, between elevations 97.95–97.75m the cumulative flake weights are less than 10g per level prior to increasing again between elevations 97.70 and 9.15m (Figure 10–1). Although this increase in flakes does not reach amounts
Figure 10–1

Clovis Pleistocene Sands
Pleistocene Terrace

Clovis Pleistocene Sands
Pleistocene Terrace

Clovis Pleistocene Sands
Pleistocene Terrace

Clovis Pleistocene Sands
Pleistocene Terrace
typical from the Clovis deposits, flakes do increase to a maximum average of 35g per level for the Lower Pleistocene Sands. Below the Pleistocene Sands, the abundance in weight of flakes decreases significantly throughout the Pleistocene Terrace, and varies little until reaching the base of the Pleistocene Terrace excavation where flakes again increase to 20g per level.

When the distribution of flakes was examined by size grade, nearly 50% of all flakes from the Clovis deposits were recovered from the 2.5 inch sieve (Table 1, Figure 10–1). Overall, there is a decrease in the percentage of Clovis flakes per level for each incrementally smaller size grade. The low percentage of small flakes from the Clovis deposits could imply the use of specific kinds of reduction activities at the site. For example, the abundance of large flakes could either be a product of the site’s positioning close to a source of raw material or reflect early stage tool production. Alternatively, the low percentages of small flakes could also reflect the removal of smaller flakes from the cultural horizon by one or more natural processes.

Below Clovis, flakes from the 1/4 inch and 1/8 inch size class increase in abundance throughout the Upper Pleistocene Sands. This percentage increase in small flakes also corresponds with a significant decrease in the percentage of large flakes from the deposits. Only 14% of the flake assemblage from the Upper Pleistocene Sands fell within the 2.5 inch size grade; a considerable reduction in quantity compared with the percentage of Clovis flakes from the 2.5 inch size grade (Table A42–1). These findings indicate a strong likelihood that postdepositional processes have led to the downward migration of smaller flakes from the Clovis deposits and into the Upper Pleistocene Sands and corroborate the findings of King (2012).

By contrast, the present analysis did identify a spike in the relative quantity of larger flakes at the base of the Pleistocene Sands. This pattern could imply that the extent of vertical disturbance did not extend below the uppermost deposits of the Pleistocene Sands at 97.55m, and

that the deeper flakes reflect a cultural component between elevations 97.00m to 97.25m.

Although it is possible that the movement of larger items could have been prohibited by the contact of the Pleistocene Terrace, resulting in an accumulation of larger flakes and artifacts on the Terrace surface, under such circumstances the distribution of artifacts should be similar between both strata. The results of analysis show that this is not the case. Nearly one-third of all artifacts greater than 2.5cm from the Clovis deposits are biface tools whereas 50% of all tools from the Pleistocene Sands of this size grade are flake tools. Because bifaces are absent from the Pleistocene Sands, unless nature is selecting against the displacement of bifaces through the stratigraphic profile, it is unlikely that the distribution of lithic items on the Pleistocene Terrace surface is the product of larger items being stopped by this surface.

Correlation Analysis: Flake Weight by Depth

A correlation analysis was performed to determine if a relationship exists between the mean weight of flakes and vertical depth (Figure 10–2). A positive correlation could indicate that post depositional processes have altered, reworked, or displaced the extant distribution from its original position of discard through winnowing, bioturbation, or fluvial activity. Figure 10–2 shows that no correlation was observed in the weight of flakes by level for the Clovis (r = 0.003; p = 0.499), Lower Pleistocene Sands(r= 0.1689; p = 0.358), and Pleistocene Terrace deposits (r =0.067; p=.344). By contrast, a positive correlation was identified for the deposits from the Upper Pleistocene Sands (r = 0.9043; p = 0.002) (Figure 10–2). The strong correlation in flake size by weight for this unit indicates sorting, and implies a greater likelihood that the deposits have been subjected to natural processes such as bioturbation.
Relationship between mean flake weight per level and depth for different stratigraphic units at Topper. There is a positive correlation in flake weight by depth for Upper Pleistocene Sands and a weak association for the Clovis, Lower Pleistocene Sands and Pleistocene Terrace.

Mean flake weight per level and depth for entire stratigraphic column at the Topper Site.
Flakes decrease in size at the base of the Clovis deposits, and into the Upper Pleistocene Sands. An increase in flake weight was observed between elevations 97.80 and 97.40m. After reaching a maximum average of 90g per level at elevation 97.40m, average flake weights tend to stabilize throughout the remaining levels of the Pleistocene Sands. Average flake weights are low throughout the Pleistocene Terrace, typically ranging between 10 and 30g per level (Table A42–2).

**Correlation Analysis: Percentage of Flake Weight by Size Grade**

An analysis was conducted to examine the average weight of flakes for each size grade per level. Flakes from the smaller size grades (e.g. 1/4 inch and 1/8 inch) tend to occur in higher percentages from the Upper Pleistocene Sands, while the Clovis and Lower Pleistocene Sands have much higher percentages of larger chert flakes (Tables A42–1 and A42–2). This distribution is illustrated in Figure 10–3, which shows the relationship of flake size by depth. There is a positive trend in artifact size grade for the Lower Pleistocene Sands (e.g. an increase in flakes of larger sizes with depth) and a negative trend in artifact size for the Upper Pleistocene Sands (e.g. a decrease in flakes of larger sizes with depth). Given these results, the likelihood is greater that flakes of small sizes are migrating downward through the stratigraphic profile from the Clovis deposits and into the Upper Pleistocene Sands than there is for artifact migration through the Lower Pleistocene Sands. The same pattern is not evident when the Upper and Lower Pleistocene Sands are compared. There is little evidence for the movement of flakes between the Upper and Lower Pleistocene Sands.

To test if there is a statistical significance in the distribution of flakes by size grade for the Clovis and Pleistocene Sands, a Pearson’s correlation test was performed comparing the percentage of total flake weight per size grade from the Clovis deposits against each underlying
Figure 10–3.
Percentage of flakes by size grade for the upper (blue) and lower (red) Pleistocene Sands. There is a decrease in the weight of smaller flakes with depth. Higher percentages of larger flakes occur in the Lower Pleistocene Sands.
stratum. This test was done to evaluate how well the Clovis flake assemblage compares to the other presumptive flake bearing deposits onsite (Table 10–1). For this test, a positive correlation between two units would imply that the percentage of flake weight per size grade for each compared assemblages is similar. Since the Clovis deposits reflect a known cultural horizon, it is assumed that the stronger the correlation between the two assemblages, the greater the likelihood that the underlying assemblage also reflects a cultural occupation. By contrast, a negative correlation would indicate that the percentage distribution of flake weight by size grade for each assemblage was dissimilar.

When the Clovis assemblage was compared to the Upper Pleistocene Sands, the correlation analysis resulted in an r coefficient of 0.203 implying that the association between the two variables is weak. The relationship between the Clovis and Lower Pleistocene Sands deposits resulted in an r value of 0.332. Although this value is slightly higher, the r value only reflects a moderate positive relationship between the two variables. When the Clovis and Pleistocene Terrace deposits were compared, the correlation analysis resulted in an r value of –0.461, implying a negative association between the two assemblages. A fourth analysis compared the Upper Pleistocene Sands to the Pleistocene Terrace and shows a strong positive correlation (Table 10–1). The results of these analyses show that the Clovis and Lower Pleistocene Sands deposits exhibit the greatest strength in similarity, although still comparatively weak.

Correlation Analysis: Comparing Flake Size Grade by Depth

Flake size is an important attribute that can inform about the potential for site disturbance. Small debitage is more susceptible to movement by natural processes such as bioturbation and fluvial activity. By contrast, increasingly larger items are more likely to stay in place when subjected to the same natural site formation processes responsible for the movement
of smaller items. Because successive stages of the lithic manufacture process have been considered to result in flakes that are progressively smaller in size, it follows that in areas where all stages of the lithic reductive process may have been carried out, barring mixing, there should exist flakes of a variety of size grades. Overtime, if similar reductive activities were occurring on-site, and controlling for the effects of raw material variability, admixture, and differential flint knapping styles, there should be little change in the distribution of flake debris by size grade. This should result in an absence of well sorted deposits, and consequently a lack of correlation in artifact size grade through the stratigraphic profile. In essence, a change in the abundance of flakes of large (2.5inch) size grades should not necessitate a change in the abundance of flakes of small size grades. Potential evidence for site disturbance is more likely indicated by: 1) high peaks of large flakes in a given level followed by 2) high peaks of small flakes in subsequent levels (a potential consequence of bioturbation or artifact translocation by fluvial activity). The size grade analysis operates under the assumption that a positive correlation in the distribution of flakes by size reflects disturbance by natural processes or if cultural, then alternative patterns of reduction intensity. A negative or neutral association indicates an absence of disturbance. Once an archaeological assemblage has been subjected to processes that result in artifact alteration or mixing, the use of mass analysis is no longer suitable for informing about lithic reductive activities at the site (Andrefsky 2006).

The distribution of artifacts for each size grade at Topper were compared and subsequently cross-tabulated against the vertical profile to determine if a significant correlations exists between the distribution of artifact size classes through time (Figure 10–4). There is a moderate positive correlation (Pearson’s) for the Clovis deposits indicated by the low density of large flakes at the base of deposits. Apart from the 2.5inch size grade, there is a lack of
Results of size grade analysis showing the variation in artifact weight by depth for the Clovis, Upper and Lower Pleistocene Sands, and Pleistocene Terrace. The variation in flake weight by size grade is strongly correlated with depth for the Upper Pleistocene Sands indicating that these deposits were likely subjected to post depositional processes.
corresponding flake size increase or decrease throughout this stratigraphic profile (Figure 10–4). By contrast, flakes of all size grades are strongly correlated by size from the Pleistocene Sands. Both small and large flakes increase in weight concurrently with each successive level and the flake deposits are well sorted. These findings imply that postdepositional processes were likely responsible for reworking the deposits of the Upper Pleistocene Sands. The flake deposits from the Lower Pleistocene Sands differ significantly from the Upper Pleistocene Sands. Figure 10–4 demonstrates no correlation in flake size by depth, indicating that post depositional processes are less likely to have altered the original contexts of the flakes from these levels. Likewise, the distribution of flake sizes from Pleistocene Terrace does not show evidence for a positive correlation between the large and small flakes.

To evaluate variation in flake size in greater detail, a Pearson’s correlation coefficient analysis was conducted to statistically examine the linear relationship between large and small flake sizes through the stratigraphic profile at Topper (Figure 10–5). There is a moderate positive correlation in small and large flakes for the Clovis deposits. There is only a slight tendency for a change in the abundance of flakes from the 2.5 inch size grade where there is a corresponding change in the number of flakes from the 1/8 inch size grade. The Clovis deposits are thus not likely to have been heavily disturbed by postdepositional processes. By contrast, the Upper Pleistocene Sands have an r value very close to 1 reflecting a strong positive correlation (Figure 10–5). This pattern shows that variation in large flake sizes tend to correlate directly with variation in small flake sizes throughout the stratigraphic deposit. This discovery supports the results in Figure 10–4. Downward movement of flakes is likely when small flakes are consistently placed in a lower stratigraphic position compared to the frequency peaks of larger flakes, suggesting that they were originally deposited in the same levels, but that the smaller
Results of a Pearson correlation test showing the linear relationship between the masses of large and small flakes in different portions of the stratigraphic profile at Topper. The low r value for the Lower Pleistocene Sands indicates an absence of vertical movement of small flakes across this portion of the stratigraphic deposit whereas the high r value for the Upper Pleistocene Sands indicates a greater likelihood of displacement throughout this strata.
Results of a Pearson correlation test showing the linear relationship between the masses of large and small flakes for the entire stratigraphic profile at Topper.
pieces were subsequently displaced downward. The line graph in Figure 10–6 shows this pattern and implies that small flakes from the base of the Clovis deposits are likely being redepsoited into the Upper Pleistocene Sands.

The analysis of the Lower Pleistocene Sands produced a low r value indicating a weak positive correlation for large and small flake size (Figure 10–5). Where there is a change in the quantity by weight of flakes from the 2.5 inch size grade, there is little corresponding change in the quantity of flakes from smaller size grades. Between elevations 97.50 and 97.25m there has been little movement of heavier or lighter artifacts through the sediment matrix compared with the overlying Upper Pleistocene Sands. An examination of the frequency peaks by size grade for the Lower Pleistocene Sands shows that the peaks for large and small flakes are in alignment, indicating that flakes from the smallest size grades are not being redepsoited (Figure 10–6). The absence of a strong positive Pearson’s correlation for the Clovis and Lower Pleistocene Sands supports the conclusion that postdepositional processes have affected these deposits to a lesser extent than the Upper Pleistocene Sands.

It should be noted that a lack of evidence for vertical movement of flakes within the Lower Pleistocene Sands deposits does not imply that these units have not been subjected to alternative processes that might have 1) led to the horizontal displacement of some existing cultural assemblage from off-site contexts, or 2) led to the creation and subsequent deposition of naturally formed flakes by fluvial or colluvial processes. To examine these possibilities in greater detail, it was necessary to perform a size grade analysis of the distribution of all cortical and quartz materials and to subsequently compare the results to the extant distribution flakes at the site.
The weight (y-axis) in flakes of large and small size grades by level (x–axis) through the Clovis and Upper Pleistocene Sands. Levels with spikes in flake weight for each size grade are depicted as arrows. Spikes for small size grades are offset relative to large size grades indicating extent of artifact displacement.

Distribution of flakes from the Lower Pleistocene Sands. There is no offset in the placement of spikes of flake quantity by weight for the 2.5 inch and 1/8 inch size grades from the Lower Pleistocene Sands deposits. Small flakes have not been redeposited relative to large flakes.
Mass and Size Grade Analysis: Distribution of Quartz Pebbles

In addition to flakes, all quartz pebbles were passed through nested screens to assess the presence and degree of fluctuation in quartz size by vertical depth. The distribution of quartz by weight for each size grade from the screened sample is presented in Figure 10–7. Quartz pebbles vary significantly by size throughout the stratigraphic profile at Topper. The largest quartz pebbles (1 inch or larger) occur with the greatest frequency from the base of the Pleistocene Terrace deposits, and are infrequent in the Holocene and Clovis deposits, and rarely comprise more than 40g of material per level in the Pleistocene Sands.

By contrast, quartz pebbles that are 1/4 inch or smaller in size occur with the greatest frequencies in the Pleistocene Sands and to a lesser extent at the base of the Pleistocene Terrace. Quartz was rarely identified from the Clovis deposits, only occurring in significant quantities from the base of the cultural deposits. Below Clovis, the distribution of quartz dramatically increases in abundance throughout the Upper Pleistocene Sands, predominantly occurring in size grades that are small, and less than 1/4 inch in size. The base of the Pleistocene Sands is characterized by a reduction in quartz pebbles of all size grades to the contact with the Pleistocene Terrace (Figure 10–7). However, the underlying Pleistocene Terrace deposits are distinguished by a fining up sequence whereby smaller quartz pebbles are present in greater quantities from the Upper Terrace deposits and larger pebbles occur in high frequencies from the Lower Pleistocene Terrace.

As a supplement to these findings, a Pearson’s correlation analysis was performed to determine if there exists any relationship in the weight of quartz pebbles for each level by depth. There is a weak to moderate positive relationship between the abundance of quartz pebbles and depth. For the Clovis, Upper Pleistocene Sands, and Pleistocene Terrace, the abundance of
Figure 10–7
Distribution of quartz by average weight per level for each size grade.
Relationship between quartz pebble weight per level and depth (g) for different stratigraphic units at Topper (at top). Results demonstrate a weak to moderate positive correlation in quartz pebble weight by depth for all units sampled. Quartz pebbles decreases in weight with depth throughout the Lower Pleistocene Sands, and increases in weight for all other stratigraphic units. The decrease in average quartz weight for the Lower Pleistocene Sands indicates a greater likelihood that these deposits were not subject to displacement by way of fluvial activity.
Figure 10–8B
Relationship between average lithic weight (g) per level, and depth for combined stratum at Topper.
quartz pebbles increases per level. For the Lower Pleistocene Sands, quartz pebbles were found to decrease with depth. Quartz pebbles from the base of the Pleistocene Sands occur in approximately the same frequency by weight they do from the base of the Clovis deposits. The decrease in average quartz pebble weight for the Lower Pleistocene Sands corresponds with an increase in flake weight and increases in larger flake sizes for these levels.

To test if there is a statistical significance in the distribution of quartz pebbles by size grade for the Holocene and Pleistocene deposits, a Pearson’s correlation test was performed. This test examined the linear relationship between large and small quartz pebbles through the stratigraphic profile at Topper. For this analysis, quartz pebble weight by level for the largest size class (1.0–2.5 inch) were compared to quartz pebble weight from the smallest size class (1/4 to 1/8 inch) for each individual unit. A positive correlation means that as the weight of large quartz pebbles increase, so too does the distribution of small quartz pebbles. An absence of correlation is indicated by an increase in the weight of one size grade relative to the other. A negative correlation is indicated by an increase in the weight of one size grade with a corresponding decrease in the weight of the other size grade. This analysis operates under the assumption that a positive correlation in the distribution of quartz pebble weight by size reflects a higher probability of disturbance by natural processes. The results of the Pearson’s correlation analysis are presented in Figure 10–9. There is a weak association in the Holocene and Clovis deposits. The weight of quartz pebbles does not vary by one size grade relative to the other through the stratum. There is a weak positive relationship for the Upper and Lower Pleistocene Sands, although the relationship is stronger for the Lower Pleistocene Sands (Figure 10–9). By contrast, the relationship between the weight of small and large pebbles through the stratigraphic profile is
Results of a Pearson's correlation test showing the linear relationship between large and small quartz pebbles (by size grade) in different strata at Topper. The $r$ value for the Pleistocene deposits reflect a moderate positive correlation suggesting a tenancy for high $X$ variables to correlate with high $Y$ variables. $r$ values for the overlying Holocene deposits are lower indicating an absence of correlation in large and small quartz pebbles. $r$ values increase with depth. $r$ values close to 1 indicate areas of the profile that have been size sorted by weight. Compare with correlation of flakes in Figure 10–5.
much stronger for the Pleistocene Terrace. As there is an increase in pebbles from the 2.5inch size class there is a corresponding increase in the distribution of smaller pebbles (Figure 10–9).

**Mass and Size Grade Analysis: Distribution of Cortical Pebbles**

The distribution in weight of cortical pebbles by size grade is presented in Figure 10–10 and in Tables A42–4 and A42–5). Based on the graph it is evident that cortical pebbles vary significantly by quantity and by size throughout the stratigraphic profile at Topper. The Clovis deposits are characterized by large quantities of cortical pebbles from the largest (2.5 inch) size class, minute quantities of cortical pebbles from the 1inch, 1/2inch, and 1/4inch size class, and moderate quantities of pebbles from the 1/8 inch size class.

Below the Clovis deposits there is a significant decrease in the amount of cortical pebbles of large size classes from the Upper Pleistocene Sands compared with the Clovis deposits. This distribution is followed by an abrupt increase in cortical pebbles of larger sizes throughout the Lower Pleistocene Sands. The abundance of large cortical pebbles is low throughout much of the Pleistocene Terrace, but increases significantly at the Pleistocene Terrace base. This pattern forms an equivalent association with the “fining upwards” sequence Harris (2010) has identified from the particle size analysis of the Pleistocene Terrace formation for sediments.

To examine the distribution of cortical pebbles in greater detail, a regression analysis was performed to determine if there exists any relationship in the cumulative weight of cortical pebbles for each level by depth. The results of this analysis are presented in Figure 10–11 and show that there is a decrease in the mean weight of cortical pebbles with depth (regardless of size) throughout the Clovis and the Lower Pleistocene Sands. By contrast, cortical weight was found to increase with depth throughout the Upper Pleistocene Sands and Pleistocene Terrace (Figure 10–11).
Figure 10
Distribution of cortical pebbles by average weight per level for each size grade.
Relationship between cortical pebble weight (g) and depth for different stratigraphic units at Topper. Results demonstrate a weak correlation for the Clovis and Lower Pleistocene Sands deposits, a strong positive correlation for the Upper Pleistocene Sands and a moderate positive correlation for the Pleistocene Terrace. Cortical pebbles decreases in abundance with depth for the Clovis and Lower Pleistocene Sands, and increase for all other stratigraphic units.
A Pearson's correlation test was performed to evaluate the linear relationship between large and small cortical pebbles through the stratigraphic profile at Topper and is employed to assess the potential that the assemblage has been subjected to natural disturbance (Figure 10–12).

When the distribution of large and small Clovis cortical pebbles was examined, there is no correlation in cortical pebble weight for the two size grades (Figure 10–12). Directly below the Clovis deposits, the Pearson’s correlation test for the Upper Pleistocene Sands revealed a very weak positive association implying very little change in the distribution of small cortical pebbles when associated with an increase in the amount of large pebbles. The Lower Pleistocene Sands exhibit a weak negative association. Accordingly, increases in the amount of large cortical pebbles at the contact with the Pleistocene Terrace weakly correlate with decreasing quantities of small pebbles. When the Pleistocene Terrace was examined, the results of the Pearson’s correlation test show a strong positive correlation (Figure 10–12). These results confirm that increases in the distribution of larger cortical pebbles throughout the Pleistocene Terrace correlate with similar rates of increases in smaller pebbles and that the deposits could be sorted by size.

**Interassemblage Comparison of Flakes, Quartz and Cortical Pebbles**

King (2012) noted that the Pleistocene Sands have considerable quantities of quartz and cortical pebbles that may have resulted from high energy input by stream flow. Based on the Mass and Size grade analysis from the present study, flakes from multiple size grades were found to co-occur with quartz pebbles and cortical pebbles from the Upper Pleistocene Sands, suggesting the potential for disturbance of this depositional unit. These findings are important given that the arrangement of flakes in archaeological contexts are often considered more likely to be modified in high energy settings than under low-energy environmental conditions.
Results of a Pearson correlation test showing the linear relationship between large and small cortical pebbles (size grade) in different strata at Topper. The $r$ value for the Pleistocene Terrace reflects a strong positive correlation suggesting that increases in large pebbles correlate with increases in small pebbles and vice versa.

Figure 10–12
Figure 10–13
Distribution of cortical pebbles by 1/8 size grade (A) and quartz pebbles by 1/8 size grade (B).
Petraglia and Potts (1994) caution, however, that low-energy systems can also be responsible for the translocation of high percentages of smaller items from their original archaeological settings. It is reasonable to assume therefore that site disturbance by high energy systems should correlate with the co-occurrence of large quartz pebbles (as input from fluvial deposition) and a mix of both small and large flakes. By contrast, low-energy systems should result in the co-occurrence of quartz pebbles with flakes of larger size grade as low-energy environments can transport small particles. Unaltered assemblages should exhibit little evidence of size sorting and should occur in association with fine grained sediments. In cases where the potential for sediment consolidation is high, large quartz or cortical pebbles should correlate with flakes and flake fragments of small sizes that may have broken as the result of increased load application from the weight of the overlying sediment.

King noted a positive correlation in the distribution of small debitage with quartz pebbles from the Pleistocene Sands, indicating that the cultural and non-cultural material components were likely deposited at the same time (King 2012:120). However, an extensive examination of a much larger sample of materials from the block excavation from the present study shows that: 1) A higher percentage of flakes occur from the Lower Pleistocene Sands than from the Upper Pleistocene Sands (Table A42–1) and such flakes are found in deposits of decreasing percentages of quartz pebbles by weight; 2) The highest density of quartz pebbles occur from the Upper Pleistocene Sands (A42–3). Based on the size grade analysis performed on the flake assemblage described above, it appears that flakes are differentially distributed throughout the stratigraphic profile at Topper, with flakes of smaller size grades occurring in higher quantities from the Upper Pleistocene Sands (and associated with higher concentrations of quartz pebbles) and larger flakes predominantly distributed in the Lower Pleistocene Sands, and at the contact with the
Pleistocene Terrace surface in sediments with reduced quartz pebble content. This relationship suggests that the Pleistocene Sands have undergone differential processes of deposition resulting in multiple assemblage configurations. In the section below the degree to which flakes correlate with quartz and cortical pebbles with regard to morphological attributes of weight and size is examined.

Flakes and Quartz

Two regression analyses were conducted to determine if there was any relationship between the amount of lithic debitage by size grade and the co-occurrence of quartz pebbles. The first analysis (Table 10–2) compared the average weight (for each level within a given stratum) for each size grade of flakes to the amount in weight of quartz pebbles for each corresponding size grade. A positive correlation in the distribution of quartz pebbles and flake weight by size grade is considered evidence that the deposits are well sorted and are likely disturbed. By contrast, a strong negative correlation indicates either disturbance by low-energy input resulting in diminished quartz weight (due to smaller quartz size) and elevated flake weights, or disturbance by high energy fluvial input resulting in elevated quartz weight and diminished flake weight. The material byproducts formed under high energy processes may also form by sediment consolidation. A lack of correlation in the distribution of quartz pebbles and flake weight implies that the processes responsible for the deposition of quartz have had little impact on the distribution of flakes.

The second regression analysis compared the average weights of quartz pebbles from the largest size grade (2.5 inch) to the average weight of flakes from the smallest size grade and vice versa (Table 10–3). A strong positive correlation between these two attributes would imply that the processes responsible for the deposition of large, heavy quartz items also likely led to the
Table 10–2
The Results of a linear regression comparing averages of quartz and flake weights per level by size grade. There is a weak correlation for quartz and flakes from the Clovis and, for most size grades, the Lower Pleistocene Sands indicated by low correlation and r values. By contrast a positive correlation is evident for the upper Pleistocene Sands.

</table>
formation of the small, light flakes from the same deposits. Sediment consolidation often leads to
the occurrence of small broken flakes associated with larger lithic bodies and is one
interpretation of a positive correlation under such a scenario. The absence of correlation implies
that the quartz deposits played little role in the formation or distribution of the flake assemblage.

The results of the linear regression analyses are presented in Tables 10–2 and 10–3. The
predominant weak correlation identified for the Clovis deposits implies that the distribution of
quartz pebbles and flakes are not associated, indicating that the deposits have undergone little
postdepositional modification by fluvial activity. By contrast, the distribution of quartz pebbles
and flakes from the Upper Pleistocene Sands demonstrate a moderate to strong association for all
size grades. These results suggest that changes in the size distribution of quartz correlate with
similar changes in flake size. The deposits have in all likelihood been reworked by fluvial
activity at some point following the point of original deposition. According to Waters, the
sediments containing these materials appear to have been deposited in “acruate channels” that
were “potentially part of a braided stream” and reflect the last time fluvial deposition occurred at
the site (Waters et al. 2009:1308)

When the distribution of quartz pebbles and flakes from the Lower Pleistocene Sands was
compared, the results indicate a weak association for most size grades (1/4inch, 1 inch, and 2.5
inch). The remaining two size grades (1/8 inch and ½ inch) reflect a moderate and strong positive
correlation respectively. These results demonstrate that the degree to which flakes and quartz
pebbles correlate within the Lower Pleistocene Sands is largely dependent on artifact size.
Accordingly, large lithic categories of quartz pebbles and flakes do not correlate by weight,
whereas small categories exhibit moderate to strong correlations. Further examination of the
regression analysis in Table 10–2 shows that the flake and quartz debris from the Pleistocene
Terrace tend to correlate for all size classes with the exception of the 2.5 inch size grade. In fact, large lithic size classes were found to exhibit weak associations for the Pleistocene Terrace compared with small size grades. This pattern is similar to the results from the Lower Pleistocene Sands.

Table 10–3 presents the linear regression comparing the average weight of large quartz pebbles to small flakes. The results of this analysis show an absence of correlation in lithic weight for both the Clovis and Lower Pleistocene Sands. This finding implies that processes leading to the deposition of quartz pebbles had no or little influence on the flake deposits from these strata. Moreover, the lack of correlation also indicates that sediment consolidation was also not responsible for the formation of the flake assemblage from the Lower Pleistocene Sands. In contrast, the Upper Pleistocene Sands exhibit a strong positive correlation. These results suggest that processes such as fluvial input and sediment consolidation are more likely to have affected or formed the flake deposits from the Upper Pleistocene Sands.

The results of the regression analysis indicate that, by size grade, the distribution of flakes and quartz pebbles from the Clovis and Lower Pleistocene Sands are most comparable. The strong positive correlation found for the flake and quartz assemblages from the Upper Pleistocene Sands is evidence that moderate energy by fluvial and/or hydraulic processes resulting in the formation of chute channels were likely responsible for the deposition and ultimately reworking of materials within the unit. Moreover, the influx of quartz pebbles indicated by the high weight content for the Upper Pleistocene Sands likely led to the removal and translocation of a portion of the small flake assemblage from the Upper Pleistocene Sands. The average weight per level of the small flake items is low compared to the average weight of small quartz pebbles and may represent the cutoff weight under which lithic items were moved.
into and out of the locality by low-energy hydraulic action, e.g. sheet wash. The quantitative ratio between the large and small fractions differs for the flake and unmodified quartz materials when the Clovis and Upper Pleistocene Sands components are compared (Table 10–3). This relationship between the large and small size grades for each lithic category implies that the small fraction of flakes from the Upper Pleistocene Sands had undergone postdepositional hydraulic winnowing (indicated by a decrease in average flake weight per level for the 1/8 inch size grade). The processes that resulted in the apparent increase in quartz pebbles is the depositional agent likely responsible for the eventual displacement of the flake deposits indicated by the predominant increase in small quartz pebbles into the Upper Pleistocene Sands.

*Flakes and Cortex*

A regression analysis was also performed to determine if there was any relationship between the amount of lithic debitage by size grade and the co-occurrence of cortical pebbles. The presence of cortical pebbles in association with flakes could be attributed to either mechanical weathering processes, or as the byproducts of lithic manufacture. For this procedure the average weight for each size grade of flakes was compared (regressed) against the amount in weight of cortical pebbles from the same size grade for each stratum. The results of this analysis are presented in Table 10–4.

*Clovis*

The regression analysis for the Clovis deposits show no correlation between the distribution of flakes and cortical pebbles from the small size grades indicating that the two assemblages are likely unrelated. By contrast, when flakes and cortex from the 2.5 inch size grade were evaluated, a strong positive correlation was indicated (Table 10–4). Based on these results, there is a positive relationship in the weight of flakes and cortex for items of the largest
Table 10–4
Results of a linear regression comparing the averages weight of cortical pebbles and flakes by size grade for each stratigraphic deposit. Correlation coefficients close to 1 indicate a strong positive correlation whereas coefficients close to 0 indicate no correlation.

</table>
size grades, implying that the conditions leading to the formation and extant distribution of these two samples could be related. Although these results could imply that postdepositional processes have altered the integrity of the deposits thus leading to the eventual size sorting by weight of all materials within the strata, the possibility also exists that these patterns may have formed as the byproduct of tool production. For example, one possible explanation for the occurrence of this association concerns the initial reduction or decortication process, whereby large, heavy cortical items are detached concurrent with primary flakes.

According to Bradbury and Carr (2004) a high average weight of materials from large lithic size grades is often indicative of biface tool production (Bradbury and Carr 2004). Since higher percentages of sizeable cortex are frequently removed from an objective piece during early stages of the biface manufacture process, it follows that such items should correlate with larger primary flakes, and occur with less frequency during latter stages of the Clovis lithic reduction sequence where smaller, lighter flakes are more common.

The variation observed in cortical pebble weight for the smaller size grades is more likely to result from natural weathering as cortical material is broken down by mechanical weathering into irregular distributions that do not correlate with flake weights for these size grades. Therefore, as flake size increases throughout the Clovis deposits (given each size grade), there is a corresponding increase in the probability that cortical pebbles weight will also correlate with flake weight.

**Upper Pleistocene Sands**

Next, the regression analysis was conducted comparing the flake and cortical pebble assemblages from the Upper Pleistocene Sands by size. This procedure demonstrated a number of alternative conclusions when evaluated relative to the results from the Clovis analysis.
described above. An examination of Table 10–4 shows a strong positive correlation between flake and cortical materials for the 1/8 inch, 1/4 inch, ½ inch and 1 inch size grades, and a weak positive correlation for the 2.5 inch size grade. These results differ, and directly contradict the results obtained from the Clovis analysis. The positive correlation in flake and cortical pebble weight across multiple size grades for the Upper Pleistocene Sands could be interpreted as evidence of artifact size sorting. The absence of correlation evident for the 2.5in size grade implies that the processes responsible for the production of large cortical items are not the same processes as those that are responsible for the production of flakes of similar sizes throughout the deposit. In summary, based on the weight and size grade analysis of the cortical and flake material, the evidence supports the notion that cultural activity in the form of lithic production is less discernible from the Upper Pleistocene Sands than it is from the Clovis bearing deposits, possibly owing to a combination of bioturbation and fluvial input.

**Lower Pleistocene Sands**

The results of the regression analysis for the Upper Pleistocene Sands show some similarities and differences when evaluated with regard to the results from the Clovis and Upper Pleistocene Sands. When cortical and flake weight were regressed for the 1/8 inch size grade, the results demonstrate a moderate positive association. When the 1/4inch size grade was evaluated, the results indicate a weak positive correlation that is comparable to the results obtained from the Clovis deposits for the same size grade. By contrast, the ½ inch size grade produced a strong positive correlation coefficient indicating greater similarity with the Upper Pleistocene Sands. The largest two size grades examined (1 inch and 2.5 inch) resulted in very weak correlation coefficients, suggesting that cortical pebble weight from the Lower Pleistocene Sands does not correlate with flake weight for the 1 inch and 2.5 inch size grades.
The results demonstrate high percentages of heavier cortical pieces and evenly distributed flake weights for the largest two size grades. As cortical weight increases across these size thresholds, there is no corresponding trend in flake weight. However, it should be noted that given the probability values, these results are not statistically significant at the .05 level ($p = 0.228$ and $0.795$). Even so, these patterns differ considerably compared against the regression analysis undertaken for the largest two size grades from the Clovis and Upper Pleistocene Sands. The weak correlation coefficients for the large size grades suggest that: 1, cortical and flake materials from the Lower Pleistocene Sands have not undergone postdepositional disturbances (e.g. agents responsible for bioturbation and size sorting have not altered the Lower Pleistocene Sands to the extent that they have for the Upper Pleistocene Sands) and; 2, the same or similar cultural lithic manufacture processes that were responsible for the co-occurrence of large, heavy cortex and flakes from the Clovis levels (primary biface core reduction) were not occurring at the time the Lower Pleistocene Sands were deposited. However, it should be noted that these results do not rule out the possibility that alternative lithic reductive technologies were responsible for the patterns of assemblage composition evident for the Lower Pleistocene Sands. Potts (2012) has found that bipolar reduction often results in flaking debris patterns that consist of high percentages of heavy cortical materials recovered from large size grades and evenly distributed weight percentages of flakes from similar size grades. The patterns from the Lower Pleistocene Sands deposits at Topper seem to best fit best with the description of bipolar reduction provided by Potts (2012).

**Pleistocene Terrace**

The distribution of all cortical and flake materials from the Pleistocene Terrace were compared by morphological attributes of size and weight. The regression analysis presented in
Table 10–4 reveals a moderate to strong positive correlation between the weight of flakes and cortical pebbles per level for the four smallest size grades. Combined with the distribution of quartz pebbles from the Pleistocene Terrace, the size grade analysis of cortical and flake weights for this unit support the conclusion that items from the smallest size grades have been moderately to well-sorted by weight. That is, the distribution of small materials has likely been disturbed to some degree by postdepositional processes. However, a weak correlation was found when the 2.5 inch size grade was examined (Table 10–4). It appears that as the size of lithic items increases throughout the Pleistocene Terrace, the degree to which materials are well sorted by weight diminishes. In other words, the weight of large Flakes and cortical pebbles is increasingly variable or patchily distributed throughout the profile. This pattern is in agreement with what Potts (2012) describes as evidence for bipolar reduction (high percentages of heavy cortical materials recovered from large size grades and evenly distributed weight percentages of flakes from similar size grades). Based on these findings, the associated distribution of large cortical cobbles and flaking debris from the Upper Pleistocene Terrace, recovered in fine grained sediments, could reflect flake/tool production by compression or anvil flaking. By contrast, the distribution of smaller flakes and cortical pebbles from basal levels of the Pleistocene Terrace are more likely to be the product of mechanical weathering or sediment consolidation than resulting from tool production.

**Chapter Summary and Conclusion**

Based on the technological analysis of the lithic items recovered from the Alluvial terrace at Topper, at least two strata have evidence of chipped stone artifacts and debris. The results of the mass and size grade analysis demonstrate that postdepositional processes are likely responsible for the formation or alteration of the lithic contents of the Upper Pleistocene Sands.
The analyses of unmodified quartz from the Upper Pleistocene Sands strongly indicate that these lithic items were introduced by fluvial activity that included moderate-energy flooding indicated by the presence of chute channels, in addition to low-energy sheet-wash originating from the hill-side slope. These processes may subsequently have led to the hydraulic winnowing of an extant assemblage of cultural lithic items as evidenced by a decrease in mean weight of small flakes throughout the Upper Pleistocene Sands thus the presence of quartz pebbles within the Upper Pleistocene deposits is most parsimoniously interpreted as a product of fluvial transport into the locality, and subsequent mixing with lithic artifacts.

The analysis also shows, however, that deposits from the Clovis and Lower Pleistocene Sands have not been subjected to recognizable post depositional site formation processes. For these deposits there is no correlation in lithic size by weight with vertical depth. At least two discrete Pleistocene Human occupation events are indicated by the results of this study. It is suggested that the first human occupation at the site post-dated the deposition of the heavy quartz fraction from the basal levels of the Pleistocene Terrace but predated the deposition of the chute channels from the Upper Pleistocene Sands. Although quartz pebbles are present from the Lower Pleistocene Sands, pebble sizes are comparatively small, with a higher proportion of larger quartz pebbles deriving from the Upper Pleistocene Sands. Moreover, a close inspection of the visible characteristic of the flake materials from these deposits found no evidence of abrasion or rounding that would imply that the flakes had been exposed to long term fluvial activity. The presence of large heavy cortical materials and associated non-rounded compression flakes of various sizes in the fine grained sediments of the Upper Pleistocene Terrace is consistent with the attributes expected from a cultural assemblage and reflects the earliest occupation of the site.
CHAPTER XI
SPATIAL ANALYSIS

Natural disturbances may have created or altered the lithic assemblages at the Topper Site. Processes such as slopewash, bioturbation, and mechanical weathering can significantly impact the vertical and horizontal integrity of the lithic deposits. Miller (2007) tested the possibility that natural processes have affected the Clovis deposits on the Hillside at Topper and found that preservation was differentially distributed across that portion of the site. A goal of the present study is to determine if the original spatial relationships between the lithic items from the research sample have been preserved. Therefore spatial analyses were conducted for all mapped lithic items in the study sample from the Clovis, Pleistocene Sands, and Pleistocene Terrace at Topper. These analyses were conducted to determine if there is any non-random horizontal or vertical patterning in the distribution of items from each assemblage. To account for the distribution of materials recovered in the screen, the screen items were examined by size across the spatial extent of the study area for each deposit.

If the Topper assemblage is a byproduct of taphonomic disturbance or represents the downward drift of flakes from the Clovis contexts above, then the spatial distribution of the assemblage should either 1) consist of a random pattern throughout the horizontal and vertical profile or 2) consist of a clustered pattern containing an accumulation of items of small size grades (due to sorting by downdrift) on a common surface if stable surfaces were encountered prohibiting the further movement of items through the profile. By contrast, a non-random (clustered) pattern, whereby items of multiple size grades co-occur, would indicate site integrity. This spatial pattern reflects an isolated, discrete, cultural deposit prior to the Clovis occupation at the site. Therefore this analysis operates under the assumption that non-random patterns within
the vertical and horizontal distribution of an unsorted assemblage should exist if: 1, the
distribution of lithic artifacts is a byproduct of human manufacture, and 2, site integrity has been
preserved.

Three analytic procedures were conducted to assess horizontal and vertical spatial
patterning at Topper; nearest neighbor analysis and k–means analysis; size grade spatial analysis;
and cluster shape analysis. The nearest neighbor and k-means analyses were conducted to
determine if the assemblages are statistically clustered and if so, to determine the number of
clusters in the distribution. The size grade spatial analysis examined the presence or absence of
spatial patterning in the horizontal distribution of flakes from different size grades across the site.
Finally, the cluster shape analysis was employed to determine if the vertical distribution of
artifact clusters were circular or elliptical (horizontal) in nature, with the assumption that clusters
conforming to a circular shape are more likely to be the product of natural formation processes.
Accordingly, chert weathering in situ in sediment will break away from the parent material in
such a way that overtime, and barring additional postdepositional processes, will form in a
“ringed” pattern around the parent material. Unlike this pattern, artifact clusters produced from
cultural processes should build up over time, resulting in cluster patterns that are elliptical in
form.

**Nearest Neighbor Analysis**

Nearest neighbor analysis operates with the assumption that non-random patterning
within a given site assemblage should occur only where the spatial array of items from the
assemblage has been preserved. Miller (2010) used nearest neighbor analysis to demonstrate the
occurrence of significant clustering of some artifact types from the Clovis assemblage on the
Topper Hillside. The present study incorporates a similar analytic design strategy. First, the
positions of three dimensionally mapped artifacts from each assemblage (Clovis, Pleistocene Sands, and Pleistocene Terrace) were projected against the vertical profile for each deposit using ArcGIS 10.2 (Clark and Evans 1954; Whallon 1974). The program designates continuous values that quantify the amount of non-random patterning within the sample. The output provides a numerical value that ranges between 0 and 2.149, with values closest to 0 indicating clustered samples. By contrast, values closest to 1 represent more randomly distributed samples whereas values greater than 1 indicate distributions that are increasingly “more regularly spaced.” (Miller 2010:48). Moreover, standard Z-scores are calculated to assess levels of statistical significance. The significance level describes the probability that a pattern could be the result of random chance. A significant-value for this study is a pattern that has less than a 5% chance of being random (α = .05).

The nearest neighbor analyses were conducted to establish the horizontal integrity of the lithic assemblages at the Topper Site. Two block excavations were chosen for the spatial analysis (Figure 11–1). These were the original 5x9 block excavation excavated from 2002–2012 that extends from N242–N250 and E136–145. All mapped items from this block have been examined with summary information presented in chapters 7–10; more specific detail on the individual artifacts is provided in the appendices. The second block excavation chosen for the nearest neighbor analysis consists of the 2000–2002 5x10m block situated adjacent to and to the south and west of the primary block. This block now extends from N236–N246 and E128–138. Only the mapped items from units N240 E130, N242 E130, N240 E132, and N242 E132 within this block have been thoroughly examined and discussed in the previous chapters.

A total of five sets of nearest neighbor tests were conducted to determine the extent of horizontal clustering. The assemblages examined include lithic materials recovered from the
Figure 11–1
Distribution of all piece plotted Clovis Artifacts (N=561). NN statistic = .779; p = <.0001.
Clovis deposits at the base of the Holocene colluvium (98.30–97.80m); the putative pre Clovis assemblage from the base of the Pleistocene Sands resting at the contact with the Pleistocene Terrace (97.70–97.00m); and lithic materials from three distinct levels within the Pleistocene Terrace that correspond with what Goodyear (personal communication) describes as three stratigraphically separated lithic reduction zones. Areas from the Pleistocene Terrace that were examined range in depth from 1) 96.90–96.70 m, 2) 96.15–95.95 m, and 3) 95.35–95.55 m. For each assemblage a nearest neighbor test was conducted first for the entirety of the assemblage, and subsequently for each tool class within each assemblage. Because the depth associated with each deposit, vertical grouping, and refit analyses were conducted to better account for the potential of vertical mixing within the deposits.

Results of Nearest Neighbor Analysis: Clovis Sample

A total of 561 plotted artifacts from the Clovis deposits were examined for spatial patterning (Appendix 43). These materials were recovered from deposits ranging in depth from 98.30–97.80 m from the study area. The nearest neighbor analysis found significant clustering for the entire Clovis assemblage (NN statistic = 0.779; p = <0.0001) (Figure 11–1, Table 11–1). Given the Z-score of –0.96, there is less than a 1 percent probability that the observed clustered pattern could be the result of random chance. The Clovis assemblage was subsequently subdivided into six groups based on tool type, and nearest neighbor analyses were conducted on each. Tool types considered for this analysis included biface tools, flake tools, production tools, core tools, bend break tools, and non-tools. The non-tool category consists of flakes and debitage.

</table>
Biface Tools

All bifaces and biface fragments (n = 77) from the Clovis deposits were examined for spatial patterning (Figure A43–2). These artifacts were combined into a single group as they provide evidence of biface manufacture. Based on the size of the block excavations, an area value of 160 was used when calculating the nearest neighbor statistic. The results of the nearest neighbor analysis show that bifaces from these deposits are significantly clustered (NN statistic = 0.7567; p = <.00001) (Table 11–1).

Clovis Flake Tools

Next all flake tools were examined for the presence of spatial patterning. A total of 179 flake tools were considered for this analysis, the most of any artifact category for the cultural deposit (Figure A44–3). Flake tools considered for this analysis include blades, scrapers, unifaces, denticulates, and modified flakes. The results of the nearest neighbor analysis found that flake tools tend to cluster (NN statistic = 0.706323; p = 0.00000. Based on the Z-score of −7.516694, there is less than 1% likelihood that the clustered pattern could be the result of random chance.

Clovis Production Tools

For the purpose of this study, production tools are considered those lithic objects used for the manufacture of stone tools and include hammerstones, hammerstone fragments, and anvils. The spatial distribution of Clovis production tools is presented in Figure A43–4. A total of twenty seven production tools were considered for the nearest neighbor analysis. The results of the nearest neighbor analysis found that Clovis production tools are clustered (NN statistic = 0.794709; p = 0.041279). However, these results demonstrate that the distribution of production
tools is more randomly distributed than biface or flake tools. Given the Z-score of –2.04, there is less than a 5% likelihood that this clustered pattern could be the result of random chance.

**Clovis Core Tools**

Next all Clovis core tools were examined to assess whether or not the distribution of artifacts represents spatial patterning. Appendix A43–5 shows the distribution of core tools from the excavation blocks considered in this analysis. The core tool category (n = 64) includes all flake, biface and blade cores, and core fragments. The results of the nearest neighbor analysis also found the distribution of core tools to be significantly clustered (NN statistic = 0.818271; p =0.005415). Based on the Z–score (–2.78), there is less than 1% chance that the clustered distribution of cores could be the result of random chance.

**Clovis Bend Break Tools**

A total of nine bend break tools were recovered from the Clovis contexts encompassed within the excavation blocks examined for this study. The spatial distribution of these bend breaks is presented in Figure A43–6. Based on the nearest neighbor analysis ( NN statistic = .1690; p = 0.0000002) the distribution is significantly clustered. Based on the Z–score (–2.78), there less than a 1% chance that the clustered distribution of bend break tools could be the result of random chance. Given the area (160sqm) from which distribution was analyzed, bend breaks are the most clustered artifact category. However, the high nearest neighbor statistic may also be due to the relatively small sample size for the artifact category.

**Clovis Non-Tools**

The Clovis non-tool category consists of all unmodified flakes and debitage recovered from the sample area. A total of 103 items were classified as Clovis non-tools. This category does not include chert cobbles and pebbles that might have formed as the result of natural
processes. When all non–tools were examined for the presence of spatial patterning, there was a clustered distribution for this artifact category (NN statistic = .654634; p = 0.0001). The Clovis non-tool category registered the lowest neighbor statistic (and least clustered) of any test for the Clovis artifact categories.

**Results of Nearest Neighbor Analysis: Pleistocene Sands Sample**

Figure 11–2 presents the spatial distribution of lithic items mapped from the Upper (97.80-97.50 m) and Lower Pleistocene Sands (97.50–92.0m). A total of 1,625 items were mapped from an area of 132 square meters. The deposits were further separated into two vertically restricted samples to see if any spatial patterns exist within the deposits that could indicate vertical mixing. A total of 1,362 items were part of the study sample and include 423 piece-plots from the Upper Pleistocene Sands and 939 piece-plots from the Lower Pleistocene Sands. When the total distribution was examined using the nearest neighbor analysis, the results show significant clustering (NN statistic = .645695; p = 0.000) for the entire pre Clovis assemblage from the Pleistocene Sands deposits (Table 11–1). In addition to examining the assemblage as a whole, the spatial patterning of individual tool classes from the Pleistocene Sands was also considered using the nearest neighbor analysis. Individual tool classes analyzed include flake tools, core tools, production tools, bend break tools, non-tool flakes and debitage, and cobble/pebbles. Apart from a single specimen, Bifaces were absent from the Pleistocene sands.

**Pleistocene Sands Flake Tools**

All flake tools from the Pleistocene Sands were examined to assess their spatial relationship within the site grid (Figure A43–8). Flake tools considered for this analysis, and recovered from the Pleistocene sands include blades and blade fragments, scrapers, unifaces,
Figure 11–2
Distribution of all pre Clovis mapped items from the Pleistocene Sands. (97.70–97.20m; n=1625).
denticulates, modified flakes, and burins. A total of 175 flake tools were identified from these deposits. When the spatial patterning of flake tools was examined, there is a clustered distribution (NN statistic = 0.745219; p = 0.000). The spatial distribution of flake tools is non-randomly dispersed across the block excavation.

**Pleistocene Sands Bend Break Tools**

A total of 65 bend breaks were mapped from the Pleistocene Sands. The results of the nearest neighbor analysis show that the distribution of bend breaks is significantly clustered (NN statistic = 0.593679; p = 0.00000). There is less than a 1% chance that the clustered pattern could be the result of random chance. However, it should be noted that all but two bend breaks were recovered from the 2002–2012 5m x 9m block excavation and it is evident that prior to 2001, bend breaks were not recorded as an artifact category in the level records. As such, the spatial distribution of bend breaks presented in Figure A43–7 likely underestimates the actual number and distribution of items from the western block excavated from 2000–2002. If this is in fact the case then the nearest neighbor statistic is likely skewed towards a clustered distribution as it does not take into account the potential for the bend breaks that were not recorded as such from the early field seasons. To compensate for this issue, a second nearest neighbor analysis was conducted for the bend break category using only the areal coverage of the original 5x9 excavation (62 square meters as opposed to 132) and excluding the two bend breaks from the 2000–2002 block excavation. When the nearest neighbor analysis was recalculated using the adjusted areal parameter, the results still show a clustered distribution (NN statistic 0.866249; p = 0.039119); however, the nearest neighbor statistic is closer to 1 indicating a low likelihood that the clustered distribution is the product of random chance.
Pleistocene Sands Production Tools

A total of 80 lithic items were identified as production tools from the Pleistocene Sands deposits of the two block excavations (Figure A43–9). These include hammerstones (n = 28), battered quartz pebbles (n = 47), and anvil stones (n = 5). When the distribution of all pre Clovis production tools from the Pleistocene Sands was examined, the results demonstrate a significantly clustered pattern (NN statistic 0.505208; p = 0.000). It appears that production tools have the lowest nearest neighbor statistic for any tool category (excluding flakes and debitage) from the Pleistocene Sands. However, when just the hammerstones were considered, the nearest neighbor statistic was closer to 1 but was still clustered (NN statistic = 0.777329; p = 0.0217791).

Pleistocene Sands Core Tools

The next class of artifacts examined was the pre Clovis Core Tools. Most of these artifacts are flake cores with little evidence of formal patterning. A total of 115 lithic items were identified as cores from the Pleistocene Sands deposits of the two block excavations (Figure A44–10). Most of these items were recovered from the 2002–2012 5x9 block excavation. When the spatial distribution of these artifacts was examined, the nearest neighbor analysis for core tools resulted in a clustered distribution (NN statistic = 0.535683; p = 0.00).

Pleistocene Sands Non-Tools

A total of 256 lithic items were identified as broken flakes or debitage from the Pleistocene Sands. These items are distinguished from the flake tool category by the lack of modification observed on the flake margins. The spatial distribution of Pleistocene Sands Non-Tools is presented in Figure A43–11. Apart from the chert cobbles and pebble class, the non-tool category comprises the largest artifact category examined from the Pleistocene Sands deposits.
The nearest neighbor analysis found that non-tools are significantly clustered in the excavation blocks examined (NN statistic = 0.449510; p = 0.00). It appears that items identified as waste products of the manufacture process have lower nearest neighbor statistics compared with the tool categories. However, this pattern may be a product of the high number of artifacts classified as non-tool debitage.

**Pleistocene Sands Cobbles and Pebbles**

The final category examined was the cobble and pebble class. These lithic items can be a product of natural processes but may also have been incorporated into the cultural system to aid in the lithic manufacture process. A total of 671 lithic items were classified as unmodified cobbles or pebbles from the Pleistocene Sands deposits; the largest lithic category examined. Figure A43–12 presents the spatial distribution of cobble/pebble items from the Pleistocene Sands. Many of these lithics comprise the items Goodyear classifies as cobble clusters associated with the manufacture of bend break and microlithic tools (Goodyear 2005). As such most cobbles and pebbles are associated with lithic features identified from the Pleistocene contexts at the site. The results of a nearest neighbor analysis found the cobble pebble class clustered (NN statistic = 0.563823; p = 0.0). In addition to the items listed above, a total of 262 mapped items that were excavated from the 2000–2002 5m x10 m Pleistocene Sands block excavation were not assigned to a specific artifact category and thus were not used for the nearest neighbor analysis. The results of the nearest neighbor analyses for the Pleistocene Sands show that all artifact classes are clustered.

**Comparison of Upper and Lower Pleistocene Sands**

Because the Pleistocene Sands consist of materials from 80cm of vertical distribution, it was necessary to separate the deposits into two vertically restricted samples to see if any spatial
patterns exist within the deposits that could indicate vertical mixing. Figures A43–30 through
A43–34 present the spatial distribution of mapped artifacts from the Upper and Lower
Pleistocene Sands. A number of patterns were revealed when the two distributions were
compared. More than twice as many lithic items were identified from the Lower Pleistocene
Sands than from the Upper Pleistocene Sands. According to Table A43–2 and 3, a higher
percentage of artifacts from each lithic category were identified from the Lower Pleistocene
Sands. Although cobbles and pebbles are the most abundant lithic category for both deposits, a
much higher percentage of cobbles and pebbles were identified from the Upper Pleistocene
Sands (Table A43–3). A chi square comparison of tool types for each deposit shows a significant
difference between the two samples (Table A43 – 4A). These patterns demonstrate a decline in
artifact abundance for the Upper Pleistocene Sands when compared with the underlying strata.
Although the increase in abundance of artifacts on the Terrace surface could indicate that these
items have been displaced from above and have migrated downward through the profile, the
rarity of bifaces from the Pleistocene Sands suggests that this is not the case. The results of a
nearest neighbor analysis for the Upper and Lower Pleistocene Sands are presented in Table A43
-4B. All lithic and artifact categories for each deposit were found to cluster. Moreover, the NN
statistics for the complete assemblage from each deposit were found to be nearly identical (NN
Upper PS = .6024, NN Lower PS = .6060). However, a comparison of each artifact category
shows that core and flake tools from the Upper Pleistocene Sands have the highest NN statistics
from the deposit, whereas production and flake tools have the highest NN statistics from the
Lower Pleistocene Sands. The flake tool category was found to exhibit the greatest disparity in
NN statistic with a difference of .201813 separating the Upper from Lower Pleistocene Sands.
These results demonstrate increased clustering for this artifact category with depth through the Pleistocene Sands

*Results of Nearest Neighbor Analysis: Pleistocene Terrace Sample*

For the nearest neighbor analysis of the Pleistocene Terrace, the unit was divided into three separate 20cm thick sections; an upper section ranging from 96.90–96.70 m; a middle section ranging in depth from 96.15–95.95 m; and a lower section ranging in depth from 95.35–95.55 m (Table 11–2). As was conducted for the Holocene, Clovis, and Pleistocene Sands assemblages, each of the three terrace sections was analyzed and artifacts were broken down into six artifact categories based on tool type; bend break tools, flake tools, production tools; core tools, and non-tools. A sixth category that includes cobbles and pebbles was also examined.

</table>
Moreover, two separate block excavations were examined; the 2005–2009 Southern Terrace block, and the 2009–2012 Northern Terrace block. It should be noted that far fewer horizontal m² of Pleistocene Terrace sediments have been excavated at Topper compared with the Clovis and Pleistocene Sands deposits. For example, whereas a total of 160 m² of Clovis deposits and 132 m² of Pleistocene Sands deposits were included in the spatial analysis, an aerial extent of only 14 m² Pleistocene Terrace sediments have been excavated (6 m² for the Southern Pleistocene Terrace and 8 m² for the Northern Terrace). These factors make recognition of spatial patterning from the lower deposits at the site more difficult, if not impossible. In the following section the results of the nearest neighbor analysis for the Pleistocene Terrace deposits at Topper are presented.

**Southern Pleistocene Terrace Block**

Figure A43–13 presents the spatial distribution of lithic items mapped from the Upper Pleistocene Terrace from the Southern block excavation (96.90–96.70m). A total of 155 items were plotted from these deposits including 26 bend breaks, three cores, two hammerstones, 13 flake tools and 57 unmodified flakes and flake debris. In addition these items, 54 chert cobbles or pebbles were also mapped. The results of the nearest neighbor analysis found that the upper deposits from the Pleistocene Terrace as a whole reflect a random distribution (NN statistic = 1.334333; p = 0.00). When the spatial patterning of individual artifact categories was considered, there is a random distribution for the bend break tool (NN statistic = 1.052605), flake tool (NN statistic = 1.107944), and Pebble categories (NN statistic = 0.989961), and a dispersed pattern for the non-tool flake category (1.619239). Evidence is absent for horizontal clustering in the distribution of artifacts from the Upper Pleistocene Terrace. The spatial patterning for the Middle deposits of the Pleistocene Terrace section (96.15–95.95m) of the Southern block excavation is presented in Figure A43–14. These levels produced a total of 250 mapped items including 23
bend breaks, 22 flake tools, 133 non-tool flakes, and 72 pebbles. The results of the nearest neighbor analysis for the Middle deposits of the Pleistocene Terrace were similar to the overlying Pleistocene Terrace deposits and show a random association for most artifact categories (Table 11–1). The flake tool and bend break classes have the lowest nearest neighbor statistics (n=0.898365 and n=0.92444) but are not statistically significant (p = 0.3617; 0.488190).

A total of 266 lithic items were mapped from the lower deposits of the Pleistocene Terrace from the Southern block excavation and includes 24 bend breaks, 22 flake tools, 133 non-tool flakes and 75 pebbles. Twelve additional artifacts were classified as cores. The spatial distribution of artifacts from the lower section of the Pleistocene Terrace is presented in Figure A43–15. The results of the nearest neighbor analysis show that bend breaks exhibit a random distribution with a NN statistic close to 1 (NN statistic = 0.961122; p = 0.715583) whereas flakes tools have a lower NN statistic and are clustered (NN statistic =0.889297; p = 0.320542). The non-tool flake and pebble categories are also clustered (NN statistic = 0.912585; p = 0.0535781 and NN statistic = 0.880922; p = 0.048514 respectively). However, even where clustering was found to occur for the flake and pebble categories, only the pebble class fell within the.05 α level of statistical significance. It would appear that the higher density of mapped artifacts per square meter for the Pleistocene Terrace combined with the smaller area tested (6m²) could be resulting in the higher nearest neighbor values for this area of the site compared with the overlying Clovis and Pleistocene Sands; giving a false indication that the deposits are random. Therefore the excavation of a larger area of the Pleistocene Terrace might provide alternative results.

**Northern Pleistocene Terrace Block**

A single 20cm section of the northern Pleistocene Terrace block was examined for the presence of horizontal spatial patterning (96.90–96.70m). Only one section was selected for
analysis because the Pleistocene Terrace surface is at a lower elevation in the northern block (97.10m) than in the Southern block (97.30m), and excavation in the northern block has only reached a depth of 96.50m. Figure A43–16 presents the spatial distribution of the mapped items from the Northern block. A total of 583 artifacts were mapped from the upper deposits of this region of the site. Artifacts identified include 25 bend break tools; 32 flake tools consisting of unifaces, scrapers and blades; 178 non-tool flakes; and 347 pebbles or cobbles. The nearest neighbor analysis found a dispersed pattern for all artifact categories with the exception of the bend breaks, which were randomly distributed. Horizontal clustering was absent from the spatial distribution of artifacts from the Northern Pleistocene Terrace block excavation. The excavation of additional units to widen the footprint of this block might aid in determining whether or not the observed spatial patterns are representative of a random distribution for a much greater area of the site.

**K–Means Analysis**

The results of the nearest neighbor analyses provided evidence for non-random patterns in the distribution of artifact classes at the site. The Clovis and Pleistocene Sands exhibit the greatest evidence for artifact clustering. Having identified the presence of non-random patterns within the horizontal distribution of artifacts from these deposits, k-means cluster analysis was used to identify the optimal number of clusters (cluster solution) for each stratigraphic deposit, and to identify the horizontal spatial patterning of artifacts within each individual cluster assignment. K-means analysis searches for non-random patterns that minimize the squared distance between a cluster’s centroid and points in the cluster (Kintigh and Ammerman 1982). The optimal cluster number for each assemblage was established based on the plot of Within Sum of Squares (SSE) by the number of clusters.

Figure 11–4

496
Based on the K–means analysis, a nine cluster solution was optimal for the Clovis assemblage and a five cluster solution was optimal for the Pleistocene Sands assemblage. The results of the cluster solutions and corresponding distribution of mapped artifacts for each cluster are presented in Figures 11–3 and 11–4. To better understand the spatial patterning of individual clusters, a kernel density function was calculated to illustrate local density concentrations. The kernel density tool in ARC GIS 10.2 calculates a magnitude per unit area from point features using a kernel function to fit a smoothly tapered surface to each point. Contours reflect high and low frequencies in the data. Figures 11–5 and 11–6 present kernel density maps for each assemblage that show high density locations associated with individual artifact clusters. Clusters from each assemblage were subsequently examined by assemblage composition. Individual clusters were compared using Chi-Square analysis to determine if the contents vary in terms of the frequency of tool types and the results are presented below.

**Clovis Assemblage**

The k–means analysis identified a total of nine optimal artifact clusters for the Clovis deposits. Apart from flakes, bifaces and flake tools were on average the most common artifact category for each cluster. Table 11–3 presents the observed versus expected number of artifacts by type for each cluster. Spikes in bifaces are found in clusters three and six. Bifaces were absent from cluster four. Clusters one, two, three and six have more than the expected number of bifaces while the expected number of bifaces in cluster five is less than expected. The observed value of bifaces is close to expected for clusters four, six, eight, and nine. Therefore, clusters three and six may best be interpreted as areas of primary reduction and initial Clovis biface manufacture. When flake tools are considered, clusters one, two, six, and eight have higher than expected numbers of flake tools. By contrast, clusters three, five, and seven have less than

P = 3.53666E–56 = < 0.00001
expected numbers of flake tools. Only in clusters one and two are both flake tools and bifaces found in higher than expected frequencies. When the distribution of cores was examined, clusters three, four, and six through eight have higher than expected numbers of core tools. Interestingly, clusters that have higher than expected core tool frequencies also have higher than expected numbers of production tools (hammerstones). These findings could imply the use of hammerstones in the reduction of cores onsite. At Topper, bend break tools were only found in clusters six and seven from the Clovis deposits and only in the former cluster were they found to occur in higher than expected frequencies. Interestingly, cluster five has the highest density of flakes, yet bifaces and flake tools are absent from this area of the site. Finally, pebbles only occur in higher than expected frequencies from cluster six.

The results of the analysis can be used to make inferences about Clovis tool production behavior at Topper. Given the distribution of artifact types from each cluster, a number of patterns emerge. The results indicate at least four distinct lithic reduction activities were carried out by Clovis occupants at the site. These include 1) flake and biface production dominated by high occurrences of these artifacts in clusters one and two; 2) core reduction indicated by high densities of cores in clusters four and seven; 3) biface core reduction based on relatively high proportions of bifaces and cores in clusters three, six, and eight; and 4) flake reduction indicated by high quantities of debitage in cluster five coupled with an absence of formalized tools. The differences in the relative frequencies of tool types and flakes suggest that lithic reduction strategies during the Clovis occupation varied across the Topper Terrace. While multiple tool categories are represented throughout the Clovis deposits from the block, the relative frequencies of tool types significantly vary from cluster to cluster (p = < 0.005). Based on the results of the observed versus expected test, significant differences occur in the relative frequencies of tool
types by cluster for the Clovis deposits at Topper and based on probability (p = 2.79643E–36); these differences are not due to random chance.

**Pleistocene Sands Assemblage**

Based on the k-means analysis, five lithic clusters were identified from the Pleistocene Sands assemblage on the Pleistocene Terrace at Topper. Tool types identified from the Pleistocene Sands include bend breaks, cores, flake tools (including utilized flakes, blades, unifaces, and burins), production tools (hammerstones and anvils), flakes and flake fragments, and cobble clusters. Many of the clusters identified from the k–means analysis are associated with lithic concentrations that have been assigned feature numbers. For example, Features 77–80, 82, and 83 are associated with optimal cluster one, Feature 87 is associated with cluster three, and Features 67, 68, 86 and 88 are associated with optimal cluster five. A list of pre Clovis features and their contents is provided in Appendix 20.

Table 1–4 presents the observed versus expected artifact counts by type for each of the five optimal clusters identified from the Pleistocene Sands. Spikes in bend break tools were found in clusters two and three. Cluster two also has higher than expected frequencies of flake, core, and production tools. Below average frequencies of bend breaks was found for Clusters one, four, and five. When the distribution of flake tools was considered, the results demonstrate higher than expected frequencies of such tools from Cluster two and four, and below expected values for Clusters one, three, and five. Clusters with higher than expected numbers of cores include Clusters one, two, and four, while production tools were found to occur in high frequencies from Clusters two, three, and five. When the distribution of unmodified flakes and flake fragments was considered, flake counts were relatively lower than expected for most Clusters with the exception of cluster three. The only cluster with higher than expected cobbles
was Cluster five. Based on the comparisons, there are significant differences in the relative frequencies of artifacts between clusters (p = <0.00001).

A number of patterns are evident from an examination of the spatial distribution of specific technological activities at Topper. Based on the analysis, Cluster one contains more than expected flakes and cores, and might reflect an area of flake core production. Clusters two and four are interpreted as tool production areas based on higher than expected flake tools, core tools, and production tools including hammerstones, hammerstone fragments, and anvil stones. Cluster three has higher than expected bend breaks and production tools but lower than expected cores and flake tools. Thus Cluster three could be an area where bend break manufacture was predominant. Cluster five is interesting given the high number of production tools but generally lower than expected values for all other tool categories.

**Spatial Analysis of Artifact Size Grade: Horizontal Postdepositional Displacement**

Natural as well as cultural site formation processes can affect the spatial distribution of lithic materials (Schiffer 1983). Petraglia and Potts (1994:226) have found a relationship between artifact size and the artifact’s place of origin. Artifacts that are closer to their relative position of origin are typically larger in size than those that are recovered at some distance from the area of proposed origin. Gunn and Foss (1997:53) made similar discoveries and suggested that in aeolian deposits, artifacts greater than 5cm were more stable than those less than 5cm (Gunn and Foss 1997:53; Miller 2010). The absence of small lithics is one potential indicator for postdepositional disturbance by wind or water (Bar Yosef 1993:18). In addition to size, artifact orientation is also an indicator of postdepositional disturbance. For example assemblages that are found to share a common orientation or strike are considered to reflect winnowed deposits whereby slopewash or fluvial activity has re-oriented artifacts to a common angle.
Goodyear has suggested that chute channels with gravel lenses in the Pleistocene Sands deposits at Topper could be the result of fluvial activity as water transports lithics down-slope (Goodyear personal communication). These processes could result in the disturbance of archaeological assemblages situated within the Pleistocene Sands deposits. To date, artifact size grade data have been obtained from the analysis of the bulk screen and artifact assemblages from 24 m² of excavated sediments ranging in depth from Clovis to the base of the Pleistocene Terrace. However, data on artifact orientation (strike) have only been systematically recorded since 2005, subsequent to the excavation of large portions of the Holocene and Pleistocene Sands deposits. While artifacts were occasionally drawn in plan-view on the level forms, these records are not consistent throughout the duration of excavation. As such, in the absence of artifact orientation data, artifact size is an alternative indicator for the potential occurrence of site disturbance by postdepositional processes.

To account for the possibility of postdepositional horizontal size sorting at Topper, the relationship between large and small artifacts from the Pleistocene Sands of the primary block excavations was examined as a means to establish if there was any spatial patterning in the distribution of small artifacts across the block. The distribution of artifacts by size was examined by calculating the weight of (in grams) of flakes from the 1/2 and larger size grade, and the 1/8 size grade for the Clovis and Pleistocene Sands screen deposits. The lithics from these deposits were subsequently standardized by the area of the provenience (per m²) from which they derive to obtain a density measurement of artifact weight per square meter. The values were then projected using ArcGis 10.1 to produce chloropleth maps of the densities for each size grade by assemblage.
The results demonstrate some similarities when the distribution of 1/2 and 1/8 inch flake weights were compared across the entire block excavation. Spikes in 1/2 and 1/8 inch flake weights occur in units N242 E140 and N242 E130. By contrast, low flake weight densities were found for unit N246 E140. Based on the maps in Figures 11–7 and 11–8, some units do not show a correlation between the densities of the 1/2 and 1/8 inch size grades, suggesting variation in the distribution of flake weight by size grade. An examination of the results shows high flake weight densities for the 1/2 inch category for units N248 E140SE, N246 E138SW and N242 E142 NE. By contrast, these same units exhibit a decrease in flake weight from the 1/8 inch size grade.

There also appears to be an increase in flake weight for the 1/8th inch size grade for unit N242 E130 compared with the 1/2 inch category. The higher density of smaller flakes from unit N242 E130, the western most unit in the study, could be interpreted as disturbance by fluvial transport of flakes down slope. However, these results could also reflect variation in lithic reduction intensity. To quantify these graphical observations, linear regression was employed to compare the density of the 1/2 inch and 1/8 inch size grades for each unit. When the values of all units were compared, the densities of the 1/2 size grade were not found to predict the densities of the 1/8 inch size grades, and the R² value is not statistically significant (R² = 0.0298; p = 0.890062) (Figure 11–9).

To see if this pattern was similar at a smaller scale, the densities of the 1/2 size grade were compared against the 1/8 size grade densities for each of five 2m x 2m units and two 1x2m units. The results are presented in Figures 11–9 and 11–10. Of the seven units examined, four have good relationships between large and small artifact size grades. These units are N242 E138, (R² =0.8048, p = <0.0001), N242 E142 (R² = 0.6375, p = <0.0001), and N246 E138 and N248 E140. Units N246 E138 and N248 E140 only have two density values each that show a positive
Figure 11–7

Artifact Densities (g/m$^2$) – 1/2 Size Grade Regressed Against 1/8” Size Grade for all Pleistocene Sands units at the Topper Site (38AL123). $R^2$ value = 0.0298; $p = 0.890062$. 

Figure 11–9
Figure 11–10
Artifact Densities for 1/2” size grade flakes (y–axis) regressed Against 1/8th” size grade flakes (x axis) for select 2m x 2m units.
correlation but lack enough values to statistically conduct the linear regression. Units with poor relationships between large and small size grades are units N242 E130 ($R^2 = 0.0111$), N242 E140 $R^2 = 0.0172$, and N246 E140 $R^2 = 0.5747$. For these units, the 1/2 inch size grade failed to predict the density of the 1/8 inch size grade (Figure 11–10). Based on these results, there is no trend in slope for the horizontal distribution of flakes by size grade. For a total of 12m² of the excavation block, the density of the ½ inch size grade flakes accurately predicts the density of the 1/8 inch flakes. For the remaining three units (12m²), the density of the ½ inch size graded flakes is a poor predictor of the density of smaller flakes. Based on the relative positions of these units, there is little evidence for patterning that suggest that one deposit across the majority of the excavation block has artifact densities of larger size grades that accurately predict the density of the smaller ones. Rather, the distribution appears to be patchy. The results of this analysis demonstrate that while disturbances may have removed a portion of the flakes from some areas of the site, such processes were not responsible for the widespread disturbance of large contiguous areas of the Pleistocene Sands deposits at the site. Alternatively, other mechanisms could also explain these distributions such as the nature of the tasks being undertaken.

**Spatial Analysis of the Vertical Distribution of the Topper Assemblages**

Archaeologists often employ the technique of back-plotting the precise position(s) of artifacts within an archaeological assemblage against the vertical profile to obtain some indication of the temporal or cultural context of the assemblage. At Topper artifacts have been recovered from the hillside and hilltop excavations as well as the Pleistocene Terrace, and are susceptible to a variety of postdepositional processes which might result in artifact displacement. For example, Miller (2010) found “relatively minimal vertical movement of artifacts between stratigraphic deposits” based on the combined refit analysis and the positioning of temporally diagnostic
Figure 11–11
Profile map of the distribution of all mapped artifacts from the Holocene, Clovis (Black n = 1,185) and Pleistocene Sands (Red n = 11) units of the 2010–2011 4m x 4m block excavation. Compare distribution of pre Clovis with 2002–2012 block excavation in figure 11–12.
Figure 11–12
Profile map of the distribution of all mapped artifacts from the Holocene, Clovis (Black n = 2,898) and Pleistocene Sands (Red n = 2,991) units of the primary 2002–2012 block excavation.
artifacts in this area of the site (Miller 2007:28). Figure 11–11 12 presents the distribution mapped artifacts from the Clovis and pre-Clovis study sample at Topper. On the Terrace, one method to identify discrete intact deposits is to project the position of artifacts against their vertical profiles and to note any differences in the technological composition of the tool assemblages recovered from each deposit. This method works best when artifacts such as Clovis points that are diagnostic to a specific age bracket occur in discreetly buried intact deposits across a site. However, not all archaeological sites or assemblages contain artifacts that are temporally diagnostic. In the potential absence of temporally diagnostic artifacts, making distinctions between what represents an archaeological assemblage and what may represent a natural assemblage becomes more difficult.

An alternative method to distinguish cultural from natural deposits is to examine the spatial relationship and orientation of individual artifact clusters with regard to their shape. Lithic assemblages that occur in buried contexts as the byproduct of weathering are prone to develop distribution patterns that form spherical or circular concentrations of debris that radiate outward from the parent body when viewed in profile. Such patterns occur because sediment particles fill the void space between the detached piece and the base of the parent material and act to limit the movement of materials that break away from larger bodies as the result of weathering. Such concentrations take the form of a bulls-eye when viewed in profile. In contrast, assemblages that are the product of human behavior are often deposited on a common surface, and undergo vertical alteration once buried. Barring artifact displacement, the spatial patterning of cultural assemblages that are deposited in clusters, when viewed in profile, should be distributed horizontally as opposed to perpendicular to a common surface, and should be elongated, or elliptical in form. Therefore this analysis operates under the assumption that lithic materials
deposited on a common surface will build up in accretional formations that when viewed in profile are elongated or elliptical in form as opposed to circular.

The present analysis examined the vertical distribution of piece plotted artifacts from the Holocene, Clovis, Pleistocene Sands, and Pleistocene Terrace deposits at Topper. All items 2.5 cm or greater in diameter, regardless of the presence or absence of visible flaking were piece plotted against the vertical profile. Figures A43–18 to A43–20 present the vertical distribution of all three dimensionally mapped artifacts at 2m intervals along the E136–E144 gridlines at Topper. Figure A43–21 shows the spatial distribution of all lithic Clovis and pre-Clovis items from the Holocene and Pleistocene Sands in plan-view.

*Vertical Grouping Analysis*

To examine the vertical distribution of the Holocene and Pleistocene assemblages at Topper, the location of all piece plotted artifacts was projected in ArcGis using artifact easting and depth coordinates. Because piece plots were predicated on a size threshold as opposed to attributes of technology, the analytical protocol makes no prior assumption that a given artifact belongs to specific culture or time period. Rather, the basis for the analysis was to identify the presence or absence of spatial patterning in the vertical profile. Units analyzed include a portion of the 2000–2002 block extending from N242 E130 to N244–E132, and the 2002–2012 Primary block from N242 E138–E144 to N248 E140. A grouping analysis function in ArcGis 10.2 was employed as an exploratory tool to search for clusters in the data across the entire vertical profile at the site. Artifact piece plot z (or depth) data was used as a variable and modeled to search for the optimum number of groupings (Jain 2009). The results were subsequently compared to original artifact classifications made in the field as a goodness of fit-test to see how well the clusters matched cultural designations.
Grouping analysis cluster assignments by vertical depth for all piece-plotted artifacts (4,649) from the Holocene, Pleistocene Sands and Pleistocene Terrace units from the 2002–2012 block excavation. Five optimal clusters were identified from the grouping analysis. (Terrace surface at 97.35m along E144 gridline. Data from N242–N248).
The results of the grouping analysis are presented in Figure 11–13, which shows five optimal groupings through the vertical profile of the deposits. Optimal groupings were determined by the grouping analysis function in ArcGis 10.2. Interestingly, these groupings correlate with five stratigraphic deposits from the site: 1) Holocene and Clovis Colluvial Sands, 2) Pleistocene Sands, 3) Upper Pleistocene Terrace, 4) Middle Pleistocene Terrace, and 5) Lower Pleistocene Terrace. One requirement for the analytic protocol calls for the inclusion of data excavated from contiguous units. Because data from the E134–E136 block were not thoroughly examined, it was necessary to omit from the grouping analysis the 2m x 2m units between grid–coordinates E128–E134. Their inclusion might present a false grouping signature. A43–23 shows the same artifact piece plot data, only this time classified by variation in lithic technology. Note that bifaces are exclusive to the Holocene and Upper Pleistocene Sands deposits, whereas bend breaks are absent from the Holocene and Clovis deposits. Based on initial visual observations of these maps, the five optimal groupings projected from the GIS program appear similar in form to some of the “technological groupings” associated with the artifact classifications.

It should be noted that the grouping tool is best used as a heuristic measure to present where patterns might be evident within a given set of data. As such, a closer examination of the map in Figure 11–13 shows some irregularities. For example, between the E136 and E137 gridlines, cluster one intersects with cluster two. Below this, situated in the terrace, parts of Cluster four, (highlighted in yellow) appear to associate more with Cluster three (highlighted in blue). These irregularities could stem from variations in the slope of the landform across the site which was not taken into consideration as a variable for the analysis. Despite the inconsistencies in the visual output of the grouping analysis, the results can be compared with the results of the
Figure 11–14

Figure 11–15

Figure 11–16
Vertical distribution of artifacts by type for the Holocene and Pleistocene Sands 2002–2012 5x9m excavation block at gridline N246.
spatial distribution of artifact types from each deposit to determine how well the grouping analysis predicts variation in lithic technology. Figures 11–14 to 11–16 show the vertical distribution of all mapped items by type from the Holocene and Pleistocene deposits in increments of 2m along the north gridline. A number of interesting patterns are revealed when these figures are compared with the results of the grouping analysis. First, bifaces are restricted to Cluster 1 from the grouping analysis, and are not found below 97.80m in depth. Second, bend breaks are absent from Cluster 1, but are found in all other clusters below 97.80m (n = 2 to 5). Third, cores occur in the greatest concentrations from Cluster two, which forms a linear surface from 97.50–97.40m between East gridlines E136–144. This “surface” corresponds with the slope of the top of the Pleistocene Terrace. Flake tools, flakes, and hammerstones are more evenly distributed throughout the vertical profile, while the highest density of pebbles occurs within the Pleistocene Terrace and areas associated with Clusters 3 and 4. Based on these observations the results demonstrate that spatial patterning does exist within the lithic assemblage at Topper and that the grouping analysis accurately predicts the distribution of some artifact classes at the site.

Vertical Analysis: Cluster Shape Morphology

To examine the vertical distribution of the piece plotted artifacts in greater detail, a shape analysis was performed to assess the “spatial morphology” of the distribution of lithic materials across the vertical profile at the site. In other words, lithic items that break apart from their parent material in buried natural contexts should radiate apart from the nucleus slowly over time as opposed to dropping immediately to the base of the parent body. By contrast, lithic deposits resulting from tool manufacture should result in deposits that are concentrated on a common surface with the parent material (core) as gravity precludes such detachments from being suspended in air around the circumference of the nucleus until burial. Therefore, unless being
disturbed by alternative post depositional processes, detachments resulting from lithic production episodes should be elliptical in shape when viewed in profile. Figure 11–17 illustrates cluster shape types used in this study with associated attributes emphasized.

For this analysis, lithic clusters from each assemblage (Holocene, Clovis, Pleistocene Sands, Pleistocene Terrace) were examined by shape. The greatest horizontal distance between two points within a given cluster was compared against the greatest vertical distance between two points within the cluster. A shape index was formulated by dividing the greatest vertical distance by horizontal distance and then dividing the result by 100. The mean index value for each assemblage was subsequently compared. Higher values indicate clusters that are progressively circular in morphology, whereas values closer to 0 indicate cluster morphologies that are more elliptical in shape. Table 11–6 shows the results of the cluster shape analysis by depositional unit. The mean cluster shape index value increases with depth. In other words, lithic clusters become progressively circular with depth. Lithic clusters identified from the Holocene and Clovis deposits have a mean shape index value of 18.03, lower than either the Pleistocene Sands (19.24) or Pleistocene Terrace (24.80) deposits. However, based on visual observation of these values, it appears that clusters from the Holocene and Lower Pleistocene Sands deposits are closer in morphology than they are to the clusters identified from the Pleistocene Terrace. To evaluate these results further, a linear regression was conducted comparing the cluster shape index value by depth for each deposit (Figure 11–18). Based on the R² values, the variation in cluster morphology cannot be explained by the variation in depth at a statistically significant level. Moreover, the results of a one way analysis of variance (ANOVA) to test for differences between the three mean cluster index values for each assemblage shows that each sample is
Cluster shape types used in this study to differentiate possible cultural from natural formation processes. The formula Max A(cm) or B(cm)/Z(100) is used as a shape index to quantify cluster shape morphology.

Figure 11–17
Results of shape index analysis regressed against vertical depth. (A = cumulative sample; B = Holocene; C = Pleistocene Sands; D = Pleistocene Terrace). Given the $R^2$ values, the models do not explain a statistically significant amount of the variation between depth and shape value.

$F_{stat} = 1.566251; \ p \ value = 0.219101$
completely random (p = 0.2191) (Table 1–7). Therefore there is no statistically significant relationship between cluster shape and depth from the samples examined.

**Vertical Analysis: Artifact Orientation**

Artifact orientation refers to the direction (strike) and inclination (dip) of an artifact as recorded when uncovered. Orientation can inform about potential postdepositional disturbances such as erosion, sheet wash, or bioturbation that may have altered the original context of an archaeological deposit. As mentioned above, artifact orientation data are lacking prior to the 2002 field season and most data available are from the Pleistocene Terrace and Pleistocene Sands. First the distribution of artifacts from the Pleistocene Sands and Pleistocene Terrace deposits were examined for the presence or absence of patterning in artifact strike. For this analysis, artifact orientation was measured relative to grid north. The distributions were subsequently examined for either a random or non–random distribution. From the primary 2002–2012 5x9 block excavation, data on artifact strike were obtained from a total of 1,182 artifacts (67 from the Pleistocene Sands and 1,115 from the Pleistocene Terrace (Appendix 38). Figures 11–19 and 11–20 present the distribution of artifacts by strike in the form of rose diagrams for the Pleistocene Sands and Terrace deposits. From these units, most artifacts failed to show any clear patterning, although a high percentage are oriented parallel to the slope of the landform and are oriented to the west at 0 degrees. However, the distribution for each assemblage can be separated into two distinct clusters.

From the Pleistocene Sands deposits, a cluster of 25 artifacts representing 37% of the assemblage have strikes between 25 and 75 degrees. To examine the distribution in greater detail, and to determine if the orientation of these artifacts is statistically different from expected, the orientations were divided into categories at 10° increments, and compared the distribution of

observed artifact strike measurements to a theoretical distribution using a Pearson’s Chi-Square test. For the theoretical distribution, it was assumed that artifacts would be randomly distributed. Following Miller (2010:41–47) an even distribution was used, since a random discard pattern would provide an equal chance that an artifact would fall into any of the angle categories. In an examination of artifact orientation on the Hillside at Topper, Miller conducted a similar test and found that artifacts conform to a non-random pattern owing to their position on the erosional zone of the hillslope (Miller 2010). Based on the analysis of the Pleistocene Sands, the observed and expected values were not significantly different ($X^2 = 0.62166$; $df=2$; $p = 0.978303$).

A second cluster of artifacts from the Pleistocene Sands ($n=10$ or $14.9\%$) were found to conform to the cardinal direction of the arbitrary grid at 0 degrees. This represents the highest percentage of artifacts for any 10 degree interval from the stratigraphic deposit. Bertran and Texier (1995:527) hypothesize that this pattern results from a subconscious tendency by people to imitate a grid when recording artifacts on a plan-view map. Miller has found the same patterns for the Clovis deposits on the Hillside at Topper and concludes that such findings “complicate the ability to statistically show that a sample is distributed randomly because there is an inherent bias towards the cardinal directions of the grid” (Miller 2007:39).

Two distinct clusters were identified from the Pleistocene Terrace based on artifact strike (Figure 11.20). The largest cluster is centered on grid coordinates that associate with the cardinal direction of the arbitrary grid at 0 degrees. The high percentage of artifacts ($n=103$; $9.237\%$) that correspond with this orientation are considered the result of human bias in the recording process. The second cluster of artifacts ranges from 35–95 degrees and consists of 334 lithic items or $30\%$ of the assemblage from the Pleistocene Terrace deposits. The orientation of these artifacts is similar to that of the cluster identified from the Pleistocene Sands. To examine the distribution in
greater detail, the orientations were divided into categories at 10° increments, and compared the distribution of observed artifact strike measurements to a theoretical distribution using a Pearson’s Chi-Square test. Based on the analysis of artifact strike for items from the Pleistocene Terrace, the observed and the theoretical distributions were significantly different ($X^2 = 22.23; df=2; p = 0.000461$). Moreover, based on the rose diagram in Figure 11–19, artifacts from the Pleistocene Terrace conform to an angle (between 0 and 75 degrees) that is aligned with the slope of the adjacent hillside at 24 degrees. Based upon this orientation, these artifacts could represent winnowed deposits where postdepositional processes have re-oriented artifacts to a common direction.

Like strike, artifact declination, sometimes referred to as dip, can also inform about post depositional processes that have disturbed archaeological deposits. Declination refers to the angle between the horizontal, or the tilt of the formation. Artifacts that are recovered at high inclinations have likely been disturbed from original contexts by downward or upward movement through the vertical profile of an archaeological deposit. Artifacts with high inclinations are often found in cracks in the sediment matrix and are an indication of disturbance. In contrast, unaltered assemblages should exhibit dips that have low angles of inclination. To evaluate whether postdepositional processes had affected the deposits at Topper, the mean inclination (dip) was examined for each stratigraphic deposit at the site. Because much of the Clovis deposits were excavated at a time prior to the systematic recording of artifact dip angles, these deposits were excluded from the analysis, and only items from the Pleistocene Sands and Pleistocene Terrace were examined. Appendix 38 provides data on strike and dip for artifacts from the study sample. Tables 1–8 and 11–9 show the mean dip for lithic items recorded from

the Pleistocene Sands (n=171) and Pleistocene Terrace (n=1504) deposits. Based on the results, artifacts from the Pleistocene Terrace have a higher mean inclination angle (18.36°) than artifacts from the Pleistocene Sands (8.87°). The likelihood that artifacts were disturbed by bioturbation is actually greater for items recovered from the Pleistocene Terrace than it is for items recovered from the Pleistocene Sands. The results of a t-test show that these means are statistically different (t-value = 4.97277; P = < 0.00001) (Table 11–8). These results are interesting given that the sediment matrix is more compact for the Pleistocene Terrace than it is for the Pleistocene Sands. One possible explanation is that the Pleistocene Terrace is more susceptible to the formation of cracks by way of wetting and drying and argilliturbation, processes that can lead to some artifact displacement over time. However, very few cracks were observed within the Pleistocene Terrace over the course of excavation, although they could have formed at some point in the past evidence of their presence has now been obscured. Moreover, bioturbation can also lead to the translocation of artifacts through the vertical profile at the site. Figure A25–8A shows a charred taproot that extends through the Pleistocene Sands and into the top of the Pleistocene Terrace. The presence of these roots in the deposits at Topper indicates increased potential for vertical movement and that flakes or other lithic items could have been disturbed from original context by natural processes at the site.

To evaluate the results in greater detail, the mean artifact inclination angles were examined for individual units within each of the two stratigraphic deposits. The results of this analysis are presented in Table 11–9. A comparison of the mean inclination angles for each stratigraphic unit shows that artifacts from the Pleistocene Sands in units N246 E138, N246 E140, and N248 E140 have inclination angles that are lower than corresponding units from the Pleistocene Terrace.
It was also found that there was considerable variation in the artifact inclination angles when all units from a given deposit were compared. The results of a One Way Analysis of Variance test (ANOVA) comparing individual 2m x 2m units from the Pleistocene Sands and Terrace deposits show a statistical difference in the mean inclination angle of artifacts recovered from each unit (Tables 11–10 and 11–11). Based on the low p values, it is unlikely that the observed differences for each unit are due to random chance and the hypothesis that all populations have identical means is rejected. The results also show that for the Pleistocene Sands, the highest artifact inclination angles (19.13°) occur in units (N246 E142) closest to the hillside slope rather than in units to the west. This pattern does not hold true when inclination angles were examined from the Pleistocene Terrace units. For the Pleistocene Terrace units, there is no trend in artifact inclination with regard to the slope of the landform. These findings suggest that artifacts from the Pleistocene Terrace were more susceptible to displacement by bioturbation or cracks in the sediment matrix than were artifacts from the Pleistocene Sands. Based on inclination angle, artifacts from the Pleistocene Sands were potentially influenced to a greater degree by slopewash from the adjacent hillside than artifacts from the Terrace. However, it is important to note that multiple agencies can produce similar patterning in the data and the configuration of the extant artifact distribution at Topper may not have been subjected to a single depositional process at a given time.

**Chapter Summary**

All lithic materials from the Topper pre Clovis and Clovis study sample were examined to assess their spatial location relative to other artifacts within the spatial grid at the site. The spatial analyses were conducted to determine if non-random horizontal or vertical patterns exist within the Topper Clovis and pre Clovis assemblages, and to aid in establishing the processes

responsible for their location of deposition. It was suggested that non–random patterns within the assemblage should exist if: 1) the distribution of lithic artifacts is a byproduct of human manufacture, and 2), site integrity has been preserved. By contrast, if the Topper assemblage is a byproduct of taphonomic disturbance or represents the displacement of flakes from the Clovis contexts above, then the spatial distribution of the assemblage would be expected to consist of a random pattern throughout the horizontal and vertical profile. Based on the nearest neighbor analysis, there is significant non-random clustering for the Clovis and Pleistocene Sands lithic assemblages. Moreover, when the samples were examined by tool type, all artifact classes from the Clovis and Pleistocene Sands deposits with the exception of the Clovis production tools were found to cluster. As such, there is non–random patterning in the distribution of mapped artifacts from the Clovis and pre Clovis assemblages at Topper. However, when the assemblage from the Pleistocene Terrace was examined, the results revealed that the distribution of mapped items was random and therefore did not follow the same pattern observed for the Pleistocene Sands and Clovis deposits. The results of the cluster shape analysis corroborate these findings, and show that the Clovis and Pleistocene Sands assemblages exhibit cluster morphologies that are elliptical as opposed to circular, and therefore are more likely the byproduct of cultural rather than natural processes. By contrast, the Lower Pleistocene Terrace exhibits assemblages that are more circular in morphology, and are less likely to be cultural. One alternative explanation for this pattern concerns the make-up of the sediment matrix. The Pleistocene Sands likely facilitate greater movement of materials within the sediment due to its loose consistency, and it is possible that displaced lithics in sandy deposits could have been reoriented into cluster morphologies that are elliptical in form. By contrast, clay is more compact than sand and could serve to hold naturally detached items in close proximity for longer periods.
A k-means cluster analysis was used to identify spatial patterning within the assemblage. Based on the k-means analysis, a nine cluster solution was optimal for the Clovis assemblage and a five cluster solution was optimal for the Pleistocene Sands assemblage. Based on the results of the observed versus expected distributions, there are significant differences in the relative frequencies of tool types by cluster for the Clovis and Pleistocene Sands deposits at Topper and based on probability, these differences are not due to random chance. The technological tool and debitage composition for each assemblage is non-randomly distributed throughout the vertical profile at the site.

Next, the relationship between large and small artifacts from the Pleistocene Sands of the primary block excavations was examined as a means to establish if there was any horizontal spatial patterning in the distribution of small artifacts across the block. Accordingly, a distribution of flakes that is well sorted by size and weight with regard to the horizontal position of a common surface is indicative of disturbance by fluvial transport. The results of the analysis found that there is no trend in slope for the horizontal distribution of flakes by size grade (1/2 and 1/8 inch). Based on these findings, post depositional processes were not responsible for the widespread disturbance of large contiguous areas of the Clovis and Lower Pleistocene Sands deposits at the site. An examination of artifact strike found that most artifacts from the Pleistocene Sands and Pleistocene Terrace are oriented in relation with the slope of the landform and are oriented to the west at 0 degrees. Based on these findings, the assemblage could represent winnowed deposits where postdepositional processes have re-oriented artifacts to a common angle after original deposition. An examination of artifact declination found that artifacts from the Lower Pleistocene terrace were more susceptible to displacement, bioturbation,
or down-drift potentially due to cracks in the sediment matrix than were the artifacts from the Clovis or Pleistocene Sands.
CHAPTER XII

Discussion: Pre Clovis at Topper?

Pre Clovis sites in North America have been identified based on combined evidence from toolkit composition, stratigraphic context, dating, paleoenvironmental data, or skeletal analysis (Dillehay 1997, 1999; Gilbert et al. 2008; Stanford et al. 2014; Waters et al. 2011). Such studies have challenged the traditional paradigm of Clovis as the first culture complex in the Western Hemisphere. The spatial distribution of potential pre Clovis sites on the landscape, if genuine, implies that humans occupied the eastern margin of North America prior to cal yr B.P. Although material culture diagnostic exclusively to pre Clovis is absent in North America prior to cal yr B.P., evidence from a number of potential sites in North America indicates that cultural manifestations distinct from Clovis could have been in place prior to Clovis. With recent discoveries of potential pre Clovis sites in the southeastern U.S. and subsequent technological analyses of associated artifact bearing assemblages, the scope of what we do know of these early inhabitants is beginning to broaden.

Although some scholars have been critical of the notion of a legitimate pre Clovis presence in North America based on present data, they acknowledge that early occupations could exist in contexts that have been obscured by the character of the assemblages themselves. Is it possible to recognize a lithic assemblage as cultural if it cannot be distinguished from the attributes that are consistently found on naturally worked cobbles? Fiedel (2013:346–347) suggests that the handful of sites that do offer the best potential for comprising a valid pre Clovis assemblage (e.g. Meadowcroft, Pennsylvania, Miles Point, Maryland, Cactus Hill, Virginia) are those that do not contain assemblages that are expedient, but rather are most similar to an Upper Paleolithic tool industry, comprised of blades and bifaces (Fiedel 2013). If lithic analysts
eliminate from possibility lithic categories that falls outside of a narrow range of reductive technologies (or what we believe an assemblage should look like), then they run the risk of missing potential evidence of material culture.

If pre Clovis peoples were incorporating multiple, distinct, or alternative lithic reductive technologies, is it possible to differentiate the tools and byproducts thereof from those that form by natural processes? If pre Clovis assemblages are “hidden in plain sight”, is it possible to identify them as such, and, if so, how would we go about it? It is the contention of this research that by broadening the search criteria to include the attributes of multiple reductive technologies, not just blade or biface manufacture, it is possible to obtain a comprehensive and more informative account of the technological organization and early prehistoric occupation (or lack thereof) of Eastern North America.

This dissertation has examined possible evidence for pre Clovis lithic technology at the Topper Site in Allendale County, South Carolina. Previous analyses of the site contents have identified the presence of conchoidal flakes from deposits that underlie a stratigraphically intact Clovis assemblage (King 2012). The these flakes, it was postulated, could result from down-drift from the overlying sediments by vertical displacement, be a product of natural fracture events by weathering, have been subjected to fluvial processes, or could reflect a legitimate pre Clovis occupation. In addition to these artifacts, items initially classified as bend break flakes have also been reported from the early deposits (Goodyear 2005). The goals of this study were to determine the origin of the lithic materials identified as conchoidal flakes from the early deposits at the Topper Site, and to test the role of human agency in the manufacture of materials preliminarily identified as bend break flakes. To address these questions a broad-based examination of the lithic attributes of a large sample of items from Topper was conducted.
Following Dincauze (1984), the claim for pre Clovis at Topper was subjected to rigorous standards through a framework of deduction that included demonstration of dating, geological and paleoenvironmental contexts, and artifact status. The site’s contents were evaluated with regard to the five criteria that Dixon (1999) suggests must be met to assess any claim of pre Clovis legitimacy. The results of this study offer a number of empirical findings regarding the legitimacy of the pre Clovis occupation at the site.

**Are there artifacts from the pre Clovis deposits at Topper that are clearly the product of human manufacture?**

Based on prior studies, artifacts of human origin in the form of conchoidal flakes have been identified at Topper (King 2012). Two hypotheses were developed to account for the presence of this flake assemblage. These flakes could represent pre Clovis evidence of flake tool production at the site. However, the potential also exists that these flakes were introduced into the pre Clovis deposit from above by bioturbation, translocation, or have formed by natural collisions through colluvial or fluvial processes. The present study demonstrates that there are flakes, broken flakes, flake fragments, and debris from the pre Clovis deposits at Topper; although the proportion of flakes to debris from these deposits is much lower than was found from the Clovis levels. Given the presence of artifacts that meet the minimum criteria for human agency below the Clovis deposits at Topper, the hypothesis that people were exploiting the site for chipped stone reduction is not rejected. A high proportion of flakes from the Clovis and Holocene deposits have attributes characteristic of biface thinning flakes; that is they are thin and curved, retain broad shallow prior detachment scars, are feathered at the lateral margins, and have multifaceted striking platforms. By contrast, flakes from flake or cobble core production are less curvilinear, and have a higher proportion of single faceted platforms. Such flakes are more
common from the Lower Pleistocene Sands and Upper Pleistocene Terrace pre Clovis deposits at Topper.

Based on the cortical and size grade analysis, a small portion of flakes (predominantly small biface thinning flakes) from the Clovis deposits have been displaced by bioturbation or displacement into the underlying Upper Pleistocene Sands. However, most of these flakes are absent from the Lower Pleistocene Sands. Given their morphology and technological attributes, most flakes from the Lower Pleistocene Sands and Pleistocene Terrace reflect cobble core and flake tool production and maintenance. Moreover, given the stratigraphic separation between the Clovis and Lower Pleistocene Sands artifact-bearing deposits, it is unlikely that the deeper assemblage has been subjected to significant bioturbation or artifact displacement. Therefore, the results of this study support the hypothesis that there is a pre Clovis component at Topper as indicated by the stratigraphically discrete assemblage of flakes and flake tools situated at the base of the Pleistocene Sands and at the contact with the Pleistocene Terrace surface. This assemblage is the product of flake tool production.

In addition to the conchoidal flakes, items preliminarily classified as bend breaks were also recovered from the pre Clovis assemblage. To evaluate whether the bend breaks were the product of human versus natural agency at the site, a lithic analysis was conducted focusing on debitage attribute analysis and flake formation. Sullivan and Rozen’s interpretation free model was employed to characterize the nature of the lithic assemblage. Bend breaks from the Lower Pleistocene Sands and Upper Pleistocene Terrace do exhibit technological attributes consistent with human lithic reductive technologies: that is, having at minimum compression rings and a detachment face. A high percentage of these items also exhibit lips along the break angle and have modification scores (e.g. Andrefsky 2013) consistent with human alteration. These items
are likely byproducts of bipolar production. However, unmodified bend breaks are more common than examples that are retouched or that exhibit microwear. As such, although bend break tools are present from the Lower Pleistocene Sands and Upper Pleistocene Terrace, the flake tool assemblage from these deposits provides the best evidence for a legitimate pre Clovis assemblage.

*Do the results indicate that there is similarity between the Clovis and pre Clovis assemblages?*

Yes and no. If peoples were not present at Topper prior to the Clovis occupation at the site, then there should be no similarity in assemblage composition between the two deposits and the debitage attributes found on materials from the site’s lower deposits (Pleistocene Sands and Pleistocene Terrace) should consist *exclusively* of amorphous debris that resulted from natural weathering processes. The results of this study provide indisputable evidence that the Clovis and pre Clovis assemblages are composed of different frequencies of debitage categories and are therefore dissimilar. Whereas the Clovis assemblage at Topper is dominated by flakes, broken flakes, and flake fragments, the pre Clovis assemblage consists primarily of debris, amorphous debris, and cortical pebbles, although conchoidal flakes are present in some quantity (predominantly from the Upper Pleistocene Sands) as well. Therefore, the hypothesis that Clovis and pre Clovis shared the same lithic manufacture strategies is rejected because there is not similarity in the composition debitage categories for both assemblages. The occurrence of conchoidal flakes from pre Clovis deposits is attributed to either flake core production or as the result of down-drift from the Clovis and post Clovis deposits into the Upper Pleistocene Sands. Based on these findings, the pre Clovis levels do not consist exclusively of amorphous debris, and therefore the materials classified as debris that contain a detachment face and compression
rings are likely the lithic byproduct(s) of tool production as opposed to natural processes. The occurrence of cortical pebbles from the Clovis deposits is interpreted as a combination of the byproduct of early stage biface manufacture and the product of artifact reorientation and weathering by sheetwash from the hillside slope. Likewise, the occurrence of cortical pebbles from the pre Clovis deposits is interpreted as a combination of the byproduct bend break production and the product of artifact reorientation and weathering by sheetwash from the hillside slope.

Flakes and flake debris associated with conchoidal fracture occur in post Clovis Holocene, Clovis, and pre Clovis contexts at Topper. The distribution and technological characteristics of this debitage throughout the stratigraphic profile is quite similar. The debitage attributes found on conchoidal flakes from the Clovis (Biface) and pre Clovis assemblages (Core and Flake tool) are consistent with known lithic reductive technologies. There is dissimilarity in the technological attributes of the flake debris from the Clovis and Lower Pleistocene Sands deposits, indicating that distinct strategies of tool manufacture were being carried out during each occupation. These results differ when considered relative to other pre Clovis sites in eastern North America where early occupants were manufacturing bifaces.

*Do the results indicate evidence for bipolar production at Topper?*

Yes. Using Cotterell and Kamminga’s model of flake formation, the lithic items that have attributes consistent with wedging, bending, and compression flaking tend to occur in greater abundances from the Lower Pleistocene Sands and Upper Pleistocene Terrace. These are the items Goodyear has referred to as bend breaks, and are most frequently classified as debris in accordance with the Interpretation Free Model. The largest bend breaks, and to those that most frequently exhibit modification, derive from the Lower Pleistocene Sands as opposed to the
Pleistocene Terrace and are spatially associated with cobble clusters, anvils, split quartz pebbles, and cobble core flakes resting at the base of the Pleistocene Sands and on the Pleistocene Terrace surface. The high percentage of cortical pebbles and tertiary bend breaks from this deposit is potential evidence of decortication in the tool manufacture process. Although items resembling bend breaks do occur from the base of the Pleistocene Terrace, it is plausible that these items in this stratum could have formed either by human agency or by natural weathering. As such, the term equifact (e.g. West 1983; see Lubinski 2014) may best be applicable to describe these items; that is that more than one single process may result in a given byproduct, and therefore the ability to distinguish between a number of potential causal agencies for an archaeological pattern is blurred (see Lyman 2004).

*Is there evidence for differentiation in toolkit composition between the Clovis and pre Clovis assemblages?*

Yes. An examination of the technological tool types recovered from Topper show that bifaces are nearly exclusively recovered from the Archaic and Clovis deposits and are absent from the pre Clovis deposits. Biface thinning flakes are largely absent below the Upper Pleistocene Sands. Flake tools, cores, and production tools occur in all stratigraphic deposits, (although at different proportions) whereas bend breaks are nearly exclusive to the pre Clovis deposits. An examination of tool form composition by stratigraphic unit found that the Clovis deposits are dominated by biface and core tools. The Lower Pleistocene Sands assemblage is composed largely of core and flake tools, and the Upper Pleistocene Terrace is composed primarily of bend break and flake tools. Based on these findings, combined with the presence of high quantities of biface thinning flakes from the Clovis deposits and smaller cobble core flakes.
from the Pleistocene Sands, it appears that the two assemblages were not produced using the same lithic reductive technologies, and there is dissimilarity in the frequency and types of tools recovered from each stratigraphic unit at the site. Given these results, the hypothesis that one or more tool types are present from the pre Clovis deposits at Topper is accepted. However, the hypothesis that the same or similar reductive technologies were carried out for both Clovis and pre Clovis deposits is rejected. The distribution and the technological characteristics of bend breaks from pre Clovis deposits are dissimilar to Clovis, being separated stratigraphically and technologically from the overlying deposits.

*Can the natural weathering of Allendale Coastal Plain chert produce morphological and technological attributes that resemble debitage formed by cultural processes, and were such processes responsible for the occurrence of bend breaks and other lithic items that might be mistaken for flakes?*

Yes and no. An experimental program was developed to test if natural processes could have been responsible for the production of lithic items that resemble cultural flakes and bend breaks at Topper. This analysis was based on the proposition that artifacts produced by humans should exhibit specific attributes that are distinguishable from the attributes that can form by experimental weathering simulations. The results of this study demonstrate conclusively that lithic detachments from Allendale Coastal Plain chert can form from multiple weathering conditions. Based on the experimental weathering simulations, Allendale Coastal Plain chert is susceptible to fracture events owing to variation and changes in the temperature and moisture content of the clay alluvial terrace deposits. Specifically, lithic cobbles from the Pleistocene Terrace at Topper can be subject to the combined effects of cyclic fluctuations in the water table and temperature, and are most prone to undergo alteration and fracture due to these weathering
processes. Specifically, immersion in water and subsequent cooling or heating lead to mechanical instability within the cobbles, and repeated cycles of this process can result in detachment.

Natural lithic fracture is most likely to occur along specific planes or cracks along the exterior of chert surfaces that denote the transition line between the submerged and exposed area of the cobble. In some instances, detached items can resemble the morphological characteristic of unmodified bend breaks and flakes, although detachments formed in this way are most similar to the items classified as amorphous debris in this study. As such, the weathering simulations did produce lithic detachments that fit the morphological description of conchoidal flakes and bend breaks. However, because the resulting detachments did not have attributes consisting of either compression rings, bulbs of force, or striking platforms on flakes (technological attributes), or compression rings or lips on bend breaks, these items should not be mistaken for the byproducts of biface, or bipolar (wedging, or compression) technologies. In other words, detachments resulting from natural weathering processes often exhibit morphological similarity to cultural debitage, but lack the technological attributes of a chipped stone reductive technology.

Although the findings in this study demonstrate that weathering processes can lead to the fracture and detachment of lithic items at Topper, the results demonstrate that the greatest evidence for fracture by weathering occurs from the lower Pleistocene Terrace. These findings are interesting given the overall pattern of differential weathering observed on cobble exterior surfaces throughout the stratigraphic profile at Topper. Artifacts from the post Clovis Holocene deposits exhibit minimal cortical weathering, whereas items from the Clovis and pre Clovis Lower Pleistocene Sands exhibit increasingly weathered surfaces with depth. These findings would seem to imply that the rate or extent of weathering can be used to denote the amount of
time in the ground. However, research also suggests that objects exposed to the elements on ground surfaces for prolonged periods will undergo more pronounced weathering than objects buried in soils (West 2010). It is therefore possible that the weathered nature of the lithic assemblage from the Lower Pleistocene Sands of unit 2b resulted from the combined influences of time in the ground as well as a prolonged period of exposure prior to burial.

Unlike the descilicified nature of the materials above, cobbles from the Pleistocene Terrace appear to exhibit differential weathering. Some items have weathered exterior surfaces and others do not. The Pleistocene Terrace maintains greater moisture content and as such, many items that are associated within these sediments have typically not undergone descilicification. Some items present little evidence of weathered surfaces whereas others appear entirely degraded. There are a number of possible scenarios that could account for these observations. For example, according to Waters et al. (2009:1303), pedogenic processes have altered the upper portion of the Pleistocene Terrace (Unit 1b) creating a weak Bt, which was subsequently truncated by erosion. Goodyear has noted that the Pleistocene Terrace surface is scoured, possibly owing to erosional processes of the river. It is possible that such processes have reworked or exposed a portion of the materials within the Pleistocene Terrace matrix.

Accordingly, items that have not undergone descilicification could have been reworked into the terrace, and the added moisture content has led to their preservation. The same erosional processes could have exposed other items from the Pleistocene Terrace to the elements for a period of time thus leading to their descilicified nature. An alternative to this hypothesis posits that the moisture of the Pleistocene Terrace led to the preservation of some chert, and that the material which has become descilicified has been vertically displaced from the overlying deposits at some point. Or it is possible that what we perceive as differential weathering in the
Lower Pleistocene Terrace is in fact the byproduct of the weathering process itself. That is, mechanical weathering has led to the fracture of lithics with already weathered surfaces, thus exposing the interior of higher quality. These interior surfaces might have the appearance ofdebitage formed by cultural processes, yet will lack evidence of impact markers.

In addition to these findings, an evaluation of the detached items from Topper using the cluster shape analysis demonstrates that clusters from the Lower Pleistocene Terrace exhibit a higher degree of vertical displacement than items from the overlying deposits. The natural items from the lower deposits are distinguished technologically from intentional bend breaks based on the attributes found on bend breaks from replicated studies (e.g. Jennings 2011) and the attributes found on modified bend breaks at Topper. Bend breaks formed by way of natural processes are most often cortical, lack compression rings or other impact markers indicating force application, and exhibit minimal retouch scars (less than 2), and have two or fewer break angles.

*Do the detachments resulting from the experimental weathering simulation compare favorably to or differ from bend breaks recovered from a known natural (control) assemblage?*

*How does the control assemblage compare to the archaeological assemblage at Topper?*

The results of the comparative analysis demonstrate that bend breaks from an off-site control assemblage are similar in morphology to items formed during an experimental weathering procedure. In addition, the bend breaks from the archaeological assemblage at Topper are also morphologically similar to items recovered from a control sample that is based on the observed attributes determined to be natural in origin. As such, it is entirely possible that natural processes could have created the Topper bend break assemblage.
Conversely, the results also show that bend breaks from the Topper Pleistocene Sands and Upper Terrace assemblages exhibit technological attributes (e.g. compression rings, lips, and modification) consistent with human agency. Based on the attribute scoring analysis, these technological attributes are absent on detachments from the control and experimental assemblages. An examination of both assemblages for the presence of differentially weathered removal scars found significantly higher proportions of such scars on the items from the control sample, with differentially weathered scars generally absent on bend breaks from Topper. This evidence precludes the notion that two or more detachments on lithics from the Topper sample were removed at multiple or distinct periods in a given artifact’s history. Where artifacts do have two or more detachments, evidence suggests the removals were struck consecutively if not within a short time of one another. When the attribute scoring analysis is considered, the Topper bend breaks generally lack cortex (86.1%), have more than two removal scars (55.2%), and exhibit modification retouch (23.9) with greater frequency than either the control or experimental assemblages. Given these results, the Topper and control assemblages may have formed under analogous conditions, but only the Topper assemblage contains items that appear to have been subjected to “technological” processes of human agency.

Do the flakes from the pre Clovis assemblage at Topper exhibit attributes that could have formed as the result of other types of natural processes apart from weathering?

Yes, research has shown that processes such as fluvial transport or contact occurring as the result of colluvial processes can produce breakage patterns and attributes on lithic bodies that include removal scars, compression rings, bulbs of force and even striking platforms that are indistinguishable from the attributes of human lithic manufacture. Experimental studies have
found that flakes complete with apparent striking platforms and bulbs of force have been produced on detachments formed from dropping obsidian cobbles from a predetermined height onto a lithic matrix below (Rutherford and Andrefsky 2013). Flakes from the pre Clovis deposits at Topper exhibit one or more of these attributes and bend breaks exhibit compression rings that could form by collisions with other lithic bodies.

Does that mean that they did? To answer this question requires a consideration of context. The Clovis debitage was recovered in association with material culture that has been shown to be diagnostic to a known period, established through technological analysis of fluted technology and radiocarbon dating. No such material culture has been reliably established for pre Clovis assemblages. However, in such instances it is essential to consider additional variables that can be employed to help differentiate between natural and cultural detachment mechanisms. For example, Andrefsky (2013) has shown that detachment scars on lithic items that occur three or more in number, are uniform, patterned in character and that occur on two to five (out of 8) segments of the object are more likely to be the product of cultural rather than natural processes. Moreover, depositional setting, lithic particle size, and orientation, among others, are also informative attributes than can be used to evaluate questionable assemblages. As such, the incorporation of multiple attributes in addition to information with regard to context is pertinent when forming interpretations about the legitimacy of pre Clovis assemblages.

Is there evidence that other natural processes, apart from the fracture of brittle solids by weathering, have led to the formation of the Topper pre Clovis flake or bend break assemblage?

Lithic items in sediments whose depositional history includes fluvial and colluvial processes are prone to battering and abrasion that can result in the formation of lithic
detachments. Items that have undergone such processes are expected to have removal scar patterns that are non-parallel, multidirectional or that occur at random angles, have rounded or abraded edges, and have removal scars that are differentially weathered. Moreover, such items should still retain some, if not a relatively high percentage of exterior cortex, and if subjected to high-energy fluvial activity, should be situated in a matrix of similar size particle clasts due to size sorting and occur in very high quantities (or at least higher than would be expected to occur from lithic reductive technologies). It is also possible for fluvial and colluvial activity to produce lithic detachments that retain some observable attributes such as compression rings, bulbs of force, and even plain striking platforms that are typically considered attributes of human agency. However, when such items do form, it is essential to consider these attributes in addition to all other attributes of the object exterior, interior, and aspects of depositional history to provide the best informed interpretation regarding the object’s formation. A depositional setting with enough energy and clasts of large enough size to remove two or more flakes from a cobbles would also be expected to exhibit fluvial or colluvial battering that did not result in the removal of flakes, and produce some rounding or abrasion resulting from the exposure to such conditions.

At Topper, the depositional unit with the greatest evidence for high energy fluvial deposition is the Upper Pleistocene Sands. This unit (top of Unit 2b) was prone to episodes of flooding and stream deposition indicated by increased levels of complete quartz pebbles presumably deposited by the Savannah River. Interestingly, this is also the unit with the greatest evidence for downward drift or bioturbation from the overlying deposits, and a lower percentage of piece plotted artifacts than the Lower Pleistocene Sands. The low percentage of material culture observed from the Upper Pleistocene Sands is an indication that either the site was not occupied with the same intensity as prior and subsequent periods, or episodes of flooding and
deposition have transported, removed, or disturbed a portion of an extant assemblage from this deposit. In contrast, flakes and bend breaks from the Lower Pleistocene Sands (lower Unit 2b) and the Upper Pleistocene Terrace (Unit 1b) do not frequently exhibit battering, rounded removal scars and margins, or abraded surfaces. Based on the condition of these items, it is less likely that they have been significantly altered by fluvial processes.

The lithic assemblage from the Upper Pleistocene Terrace is found in clay and sand that were deposited by low-energy, alluvial deposition and overbank flooding. The occurrence of lithic items of both large and small sizes, often resting on common surfaces within the matrix, and that have not been size sorted, is further indication that low-energy deposition has not significantly altered the spatial distribution of the Upper Pleistocene Terrace component of Unit 1b. Size sorting would have been expected had the items been subjected to higher energy fluvial processes. The lack of stained river stained cortex on flakes and bend breaks below the Clovis deposits is further evidence that the Pleistocene Terrace deposits very likely have not been exposed to high-energy fluvial processes.

It is possible that cracks may have formed within the Pleistocene Terrace during prior periods of aridity. However, the lack of biface production debris and absence of items that exhibit river–stained cortex within the upper portion of this unit strongly suggest that processes leading to artifact displacement (e.g., bioturbation, winnowing, down-drift) are not responsible for significant disturbance of the lithic assemblage from the Upper Pleistocene Terrace. Given this evidence, the most probable interpretation is that the pre Clovis assemblage at Topper either formed by cultural processes (e.g., artifact clusters in association with debris, flake tools, and bend breaks, and anvils from the Lower Pleistocene Sands and Upper Pleistocene Terrace), or in
some cases possibly by natural weathering as in the deposits from the base of the Pleistocene Terrace.

*Does evidence from the microwear and modification analysis support the conclusion that the Topper bend break assemblage is natural in origin?*

The trace microwear analysis supports a cultural origin for the pre Clovis Topper assemblage. For at least one attribute, residue, the results are inconclusive. Analyses show that artifacts from all stratigraphic deposits at Topper exhibit microwear or post-detachment modification. An examination of the distribution and size of modified items shows that examples from the Clovis, Lower Pleistocene Sands, and Upper Pleistocene Terrace exhibit higher percentages of attributes typically associated with cultural modification. The Index of modification analysis found a difference in the types of artifacts that exhibit modification for each stratum. Whereas flakes and broken flakes makeup the greatest percentage of modified tools from the Clovis deposits, modified items from the Pleistocene Sands are predominantly flake tools, bend breaks, flake fragments, and debris. Modified artifacts from the Pleistocene terrace are most predominantly flakes and bend breaks. Although there is an increase in the proportion of modified artifacts in the Pleistocene Terrace when compared with the Pleistocene Sands, the largest and best items suitable for use are from this unit derive from the Upper Terrace given the higher index of modification scores.

An examination of 50 artifacts at Topper for trace microwear from the pre Clovis deposits revealed micro-chipping, polish, and striations on a significant number of these artifacts. Based on these results, the hypothesis that microwear on lithic items from Topper resulted from intentional human use is not rejected. Evidence of variation in the percentage and type of microwear by strata indicates that some deposits at Topper hold greater potential evidence of
cultural activity than other deposits. The presence of micro-chipping and possibly microwear polishes on bend breaks from the Lower Pleistocene Sands and Upper Pleistocene Terrace is most probable to be the result of working materials that are medium hard, to medium soft in form. Materials that can often produce these patterns include fresh wood, bone or possibly hide.

By contrast, items from the lower deposits of the Pleistocene Terrace are more consistent with an origin formed by natural processes, and support the results of the experimental simulation study that bend breaks from the deepest deposits at the site are likely the product of natural weathering. The items from these deposits that do exhibit potential retouch scars or microchipping, when present, have scars that are typically few in number and are non-patterned. Polishes and potential residue were not observed on specimens from these deposits with the same consistency as those that were found on items from the Upper Pleistocene Terrace. There is also greater variation in lithic clast size for items recovered from the Lower Pleistocene Terrace, strengthening the possibility that lithic objects could have been struck or detached by colluvial bombardment or sediment consolidation and therefore resulting in potential attributes that resemble microchipping. Based on the occurrence of modification and microwear patterns on bend breaks, the intentional production of bend break fractures for tool use has only been inferred. The presence of compression rings, lips, and modification on bend breaks are the most parsimonious criteria for distinguishing intentionally produced bend breaks from unintentional fracture resulting from mechanical weathering processes. Moreover, it should be of note that natural processes can produce microwear that can be difficult to differentiate from cultural processes and future experimental studies are recommended to more fully interpret the results.
Is there evidence that the pre Clovis materials are in deposits within clear stratigraphic context?

Four distinct analyses were conducted to evaluate the stratigraphic integrity of the pre Clovis deposits at Topper: cortical, mass and size grade, spatial, and refit analysis. The results of the cortical analysis show that cortical materials occur in stratigraphically discrete contexts below the Clovis horizon at Topper, and that such materials are most abundant from three locales onsite: the Clovis and post Clovis Holocene deposits, the base of the Pleistocene Sands and the base of the Pleistocene Terrace excavation. Because the first two of these locales correlate with high frequencies of 1/8 inch flake debris, the associations are considered to reflect two discrete cultural occupations. The high percentage of debris and partially to fully decorticated chert cores from the Lower Pleistocene Sands recovered in association with high percentages of cortex is considered to reflect evidence of lithic manufacture associated with bipolar or flake/core production.

River stained cortex can serve as an indicator of the variation in raw material selection practices conducted at the site. The relative absence of river–stained cortex from the Pleistocene deposits at Topper is significant and is an indication that 1) river stained chert was either not widely accessible prior to the Clovis occupation, 2) that people were changing raw material exploitation practices through time, or 3) that the deposits are relatively intact with little evidence of bioturbation.

These findings also inform on the possible origin of the conchoidal flakes from the Pleistocene Sands. If there is little evidence for the bioturbation of river–stained chert through the stratigraphic profile, then it follows that the distribution of conchoidal flakes from the Lower Pleistocene Sands had also not been subjected to bioturbation, and therefore were either
deposited by flake/core or flake tool manufacture, or were introduced by fluvial input from the river. The location at which river stained cortex disappears from the stratigraphic profile serves as an indicator of the point in time at which the Savannah River transitioned from a braided to a meander system and began to down-cut through the alluvial Terrace, exposing chert to the transformation processes of the river. As such, river stained cortex can serve as a proxy for the extent of down-drift that has occurred below the Clovis deposits. The occurrence of non-weathered thermally altered flakes from the Pleistocene Sands also implies that the absence of river-stained cortex from these deposits cannot be explained as the result of weathering processes. Thus river stained cortex can be used as a proxy for the extent of down-drift that has occurred between the Clovis and Upper Pleistocene Sands.

The results of the mass and size grade analysis show that natural processes are likely responsible for the formation or alteration of the lithic contents of the Upper Pleistocene Sands by fluvial activity. However, the analysis also found that these processes had minimal effect on other areas of the stratigraphic profile, most notably the Clovis and Lower Pleistocene Sand deposits. The size grade and mass analyses for these deposits show that there is no continual decrease in the size of artifacts, debitage, or screened material throughout the stratigraphic profile and demonstrate that the pre-Clovis assemblages are not the product of down-drift. The Clovis and Lower Pleistocene Sands have not been greatly affected by post-depositional site formation processes, and the deposits are intact.

One exception to this interpretation is advanced from the results of the artifact orientation (strike) analysis. A majority of the lithic items from the Pleistocene Sands are oriented towards the west, or downslope from the hillside, implying that processes such as sheetwash or erosion
could have led to their reorientation or even displacement. Alternatively, the high percentage of artifacts with strikes of 0 degrees could also be the result of human bias in the recording process.

The mass and size grade analysis of lithic materials from the Pleistocene Terrace found that quartz and cortical materials generally increase in size throughout the profile whereas flakes, debris, and amorphous debris decrease in size. These findings could favor sediment consolidation as the mechanism responsible for the production of the extant lithic assemblage at the Pleistocene Terrace base, as a high percentage of these items were classified as amorphous debris, lack compression rings, striking platforms, and bulbs of force. Load application of sediment overburden acting on an assemblage of relatively large cortical and quartz pebbles can cause brittle solids of medium to large sizes within this matrix to fracture, (thus causing a reduction in void space), and therefore reducing in size the items that could be mistaken for lithic debitage (Eren et al. 2011, Jennings 2011). According to Andrews (2006), consolidation due to natural overburden can create artifact distributions that are not horizontally size sorted, which the Lower Pleistocene Terrace deposits do appear to be. In addition to these findings, Wildeson (1982) suggested that deposits with higher moisture content may increase the likelihood of sediment consolidation on buried artifacts. The Lower Pleistocene Terrace deposits are not only deeper, but are also prone to greater levels of saturation than all overlying deposits at Topper and therefore would also have had a greater probability of undergoing sediment consolidation at some point in the past.

Although average flake weights are generally low throughout the Pleistocene Terrace, the occurrence of three zones of increased flake size in the deposits provide evidence against the proposition that this flake assemblage represents the downward migration of items throughout the complete stratigraphic profile. The vertical integrity of the mapped deposits from the
Pleistocene Terrace appears intact. Only the Upper and possibly the Middle Pleistocene Terrace contain artifacts with attributes that are most consistent with lithic manufacture. Such artifacts include modified bend breaks, cores, cobble clusters, and flake tools. Increased amounts of piece-plotted split quartz pebbles from the Upper Pleistocene Terrace are considered evidence of production tools, used as small anvils for the production of bend breaks. Although a relatively high percentage of bend breaks from this deposit (Upper Terrace) exhibit technological attributes, only those with evidence of microwear or modification are considered to have been used as tools. By contrast, the Lower Pleistocene Terrace is dominated by small bend breaks, and natural pebbles. Combined with the results of the experimental study, there is a greater probability that the deeper Pleistocene Terrace deposits were formed by natural processes (weathering or sediment consolidation).

The spatial analysis confirms the results of the cortical and mass and size grade analysis. A nearest neighbor analysis shows that there is statistically significant non-random clustering of lithic materials from the Clovis and Pleistocene Sands. Profile maps of the distribution of mapped artifacts show an apparent distinction between the Clovis and Lower Pleistocene Sands and that these assemblages are primarily distributed with regard to common surfaces. These findings indicate that 1) the two deposits are separated in time, and 2) there is little indication for downward drift of artifacts into the lower assemblage from above.

The cluster shape analysis found that the Clovis and Lower Pleistocene Sands have cluster morphologies that are elliptical as opposed to circular in form. There is little evidence that natural processes have led to the fracture of these items in such a way that would have resulted in the vertical displacement of lithic clusters and the extant patterns are likely cultural in origin.
Items from the Pleistocene Sands that have been classified as pre Clovis artifacts are not forming as the result of the breakdown or degradation of chert over time by mechanical weathering. Evidence for horizontal clustering in the distribution of artifacts from the Pleistocene Terrace is absent. However, because of the massive quantity of mapped artifacts relative to the small horizontal area examined, these results should be considered preliminary. Future excavation to widen the footprint of the Pleistocene Terrace might aid in determining whether or not the observed spatial patterns are in fact representative of a random distribution.

The results of the k–means analyses show that there are significant differences in the relative frequencies of tool types by cluster for the Clovis and Lower Pleistocene Sands deposits, and based on probability, these differences are not due to chance. The Clovis deposits are dominated by biface, flake tools, and core tools whereas the Lower Pleistocene Sands are dominated by bend breaks, cores, flake tools, and cobble clusters. Not only is there a difference in toolkit composition between the two assemblages, but there was also found to be variation in the composition of tool types for each individual cluster within a given assemblage. Many of the features identified as lithic clusters at the base of the Pleistocene Sands could be individual activity areas where distinct tool production tasks were carried out by different individuals within the group. By contrast, these deposits could also reflect the continual use of the site over multiple return trips with slightly different tool production activities occurring with each trip. Even so, based on these results it is possible to identify and differentiate areas of the site where certain tool types were produced based on the distribution of artifact types within each lithic cluster.

Additional spatial analyses were carried out to evaluate whether or not the horizontal and vertical distribution of artifacts for each stratigraphic deposit had been subjected to
postdepositional disturbance. According to the chloropleth maps there is no trend in the horizontal distribution of artifacts by size grade. These findings support the conclusion that post depositional processes were not actively responsible for the widespread disturbance of large contiguous areas of the Clovis and Lower Pleistocene Sands. The chert cobble and artifact clusters that are distributed across the surface of the Pleistocene Terrace are patchy in size across the horizontal slope of the landform and imply that fluvial processes have not resulted in significant size sorting of the lithic deposits from the landform. Moreover, the examination the lithic items recovered from these deposits found no evidence of rounding, indicating that they have not been subjected to prolonged periods of fluvial activity. This finding suggests that the deposits from the Lower Pleistocene Sands were likely buried rapidly before the processes that lead to abrasion or rounding could have taken hold.

When the vertical association of lithic materials was considered, the highest density of quartz occurs from the Upper Pleistocene Sands, and is associated with flakes of small size grades. The deposition of quartz in these deposits could reflect a period when the pre Clovis deposits at the site were buried by fluvial sedimentation. This process could have also resulted in the removal from the Upper Pleistocene Sands of flakes from a preexisting archaeological component at Topper, the introduction of flakes to the site from a portion of an offsite archaeological component, or the creation of flakes by the collision of chert cobbles in the fluvial system. The larger and more abundant quartz pebbles from this deposit (Upper Pleistocene Sands) compared with the over and underlying deposits indicate dynamic processes associated with a braided river system and high-energy flows. According to Butzer (1982), such systems are not favorable for the preservation of archaeological components. According to Waters (1988), the systemic context of many sites situated along the banks of braided rivers is often destroyed
and subsequently transposed into a secondary context. If in secondary contexts, flakes from the Upper Pleistocene Sands could have originated from older sediments exposed on surface sites or terraces adjacent to the river bed or reflect bioturbated materials from the Clovis deposits above. In contrast to the results that characterize the Upper Pleistocene Sands, a much higher proportion of flakes and tools of larger size grades derive from the Lower Pleistocene Sands and imply that postdepositional processes were not causing a decrease in flake and bend break size through the complete stratigraphic profile at the site. These findings rule out the possibility that numerous small flakes have migrated downward through the stratigraphic profile from the Clovis deposits, leading to the formation of a layered deposit at the base of the Pleistocene Sands. The patterns of lithic distribution from the Lower Pleistocene Sands at Topper seem to best fit with the byproducts of bipolar tool production and conchoidal flakes resulting from flake/core tool production.

**Are paleoenvironmental studies consistent with ages assigned to the site?**

The paleoenvironmental history of the Topper Site was reconstructed based on two independent studies. Smallwood examined four sediment samples from the Holocene and Clovis deposits on the Topper Hillside and, based on the limited data, found evidence of a pollen sequence that is in accord with the reconstructed geochronology at the site (Smallwood n.d.). Oak dominates the upland contexts at Topper during the Clovis period with the subsequent Holocene dominated by pine, hickory, and other deciduous species. Given better preservation and higher pollen counts, Watts (1980) documented a similar sequence for this period at White Pond, S.C., to the north.

A second paleoenvironmental analysis examined the history of unit 1a from the base of the Pleistocene Terrace at Topper. Based on the dates obtained from the 2011 OSL samples,
these sediments likely predate 65,000 cal yr B.P. The results of the study demonstrate pollen preservation from the analysis of two slides from the sediment core. Higher percentages of temperate, moist thriving pollen were observed from the older, deeper sample, whereas higher percentages of boreal species were identified from the younger sample. The sequence corresponds with the transition from the Eemian Interglacial (120,000 cal yr B.P.) to a period of cooler climate between 120,000 and 65,000 cal yr B.P. Moreover, AMS radiocarbon dating of Abies and Carya taxa from sediments taken from a location near where the top of the core was extracted returned dates of 54,700 and 55,500 $^{14}$C yr B.P. which provide a minimum age of the plant materials (Waters et al. 2009). Although the results of pollen analysis could reflect a Late Quaternary transition in vegetation at Topper from warm, tolerant taxa, to species that thrive in cooler environments, it is important to note that the sample sizes examined were much too small to make this assertion, and further analyses are necessary to more fully interpret the pollen record at the site. Furthermore, no pollen analysis has reconstructed the paleoenvironmental history of the sediments that contain the pre Clovis assemblage from Unit 1b, radiocarbon dating of humic acids from these deposit have returned dates in excess of 20,000 cal yr B.P. (Waters et al. 2009). According to Waters, macrobotanical remains such as charcoal and wood are rare at Topper and therefore organic botanical materials most often occur as either lignified plant remains or as humic acids within flood basin sediments and paleosols (Waters et al. 2009). Given the paleoenvironmental analyses that have been conducted thus far at Topper, all results are consistent with the ages assigned to the site.
Are there reliable, concordant, and stratigraphically consistent absolute dates from the deposit?

Yes and no. There are discrepancies on the dates obtained from some deposits at Topper, specifically the Pleistocene Sands. Since 1998 chronological control of the geological record at Topper has been conducted through a combination of single and multiple aliquot OSL and radiocarbon dating techniques. Water’s (2011) detailed assessment of 13 radiocarbon and 18 luminescence dates obtained from the Holocene and Pleistocene Terrace demonstrate a stratigraphically consistent record of the geological history at the site. The minimum ages from unit 1a from the base of the Pleistocene Terrace range from 44,300 B.P. (+/– 1700) to 51,700 B.P. based on combined C14, single, and multiple aliquot OSL dating techniques. More recent dating of this deposit using only single aliquot OSL methods have resulted in an older maximum age of the deposit extending the age of Unit 1a to 70.7 B.P.

Dates from Unit 1b from the top of the Pleistocene Terrace range from 19,280 +/- 140 B.P. based on the Waters et al. (2009) study to 59,400 B.P. (Goodyear personal communication 2014, Figure A5–4). Initial dating of the Pleistocene Sands using single and multiple aliquot techniques resulted in an age that ranges from a 14,000 B.P. +/- 1,200 B.P. to a maximum of 14,800 B.P. +/- 1,200 B.P. (Waters et al. 2009) for the deposit. More recent dating of the deposits places an age of 34,000 B.P. for the Upper Pleistocene Sands to 62,000 B.P. at the contact between the Lower Pleistocene Sands and the Pleistocene Terrace surface (Goodyear personal communication 2014). An OSL date of 53,000 B.P. was obtained that chronologically separates the Upper and Lower Pleistocene Sands. The sediments from which these dates were acquired correspond with the distribution of chert cobble clusters on the Pleistocene Terrace surface. Based on the two separate studies, the age of the Pleistocene Sands diverge markedly.
If the results of the more recent OSL dates are correct, the age of the Pleistocene Terrace alluvium significantly predates the onset of colluvial deposition from the hillside slope. Barring postdepositional disturbance, the pre Clovis assemblage from the Lower Pleistocene Sands and Upper Pleistocene Terrace at Topper fall within Marine Isotope Stage 3, described as a period during the last glacial cycle between 60 and 27ka that experienced a number of sudden climate warming pulses known as Dansgaard-Oeschger events. Therefore, these deposits appear to reflect a pre-Last Glacial Maximum (LGM) human occupation in the southeastern U.S. The lack of bifaces and biface production debris from these pre Clovis deposits imply that the Late Pleistocene Clovis and pre Clovis assemblages are separated in age and have not been subject to down-drift. The absence of bifaces from the older deposits at the site also precludes the notion that the bend breaks were formed from snapped biface fragments, or as a result of trampling.

An evaluation of the OSL dates obtained from the 2012 sediment samples shows that the ages obtained for the Upper Pleistocene Terrace (59,400 cal yr B.P.) and Lower Pleistocene Sands (62,000 cal yr B.P.) overlap. It is also possible that the discrepancy between the two samples could simply reflect statistical overlap. One possible explanation for this discrepancy posits that the Pleistocene alluvium was deposited relatively rapidly. The Lower Pleistocene Sands and the underlying Pleistocene Terrace each represent different floodplain regimes of the Savannah River. It is possible that a rapid burial of the exposed Pleistocene Terrace surface by fluvial sedimentation from the river could have led to some mixing, with sediments of slightly different ages being redeposited in the watershed. The small temporal age bracket that distinguishes the two stratigraphic formations could explain the similarity in toolkit composition for the Upper Pleistocene Terrace and the Lower Pleistocene Sands, where modified bend breaks, flake tools and cores are common in both deposits. Because bend breaks occur in both
deposits, and because all dating efforts prior to 2011 resulted in a substantial date range that differentiated the two assemblages (15,000 cal yr B.P. to 50,000 cal yr B.P.), critics of the legitimacy of bend breaks as a cultural phenomenon have questioned how a single lithic technology could last for 30,000 years or more while undergoing little morphological or technological change. If the new dates accurately define the age of the pre Clovis deposits at Topper, and if the lithic technology of the assemblage has been accurately interpreted, then a model favoring rapid deposition and burial of what would become the Pleistocene terrace surface could adequately explain the presence of bend break tools throughout the Upper Pleistocene Terrace and Lower Pleistocene Sands without requiring a significant amount of intervening time (e.g. 2,600 years) between the deposition of each assemblage. Future investigation is warranted to confirm the age of the Pleistocene Sands.

**Is it possible to place the pre Clovis toolkit at Topper into broader behavioral context?**

Given the differences in lithic technology between the Clovis and pre Clovis deposits at Topper, the assemblages from the Pleistocene Sands and Upper Pleistocene Terrace might best be viewed as unrelated to Clovis, and should not be considered as part of a settlement subsistence system based primarily around the hunting of megafauna. Rather, the pre Clovis utilized flake tool and to a greater extent, bend break assemblage at Topper might better be described as an expedient rather than formal reductive technology, where tools could be readily and quickly produced on an as needed basis. Expedient technologies are those that do not typically adhere to a pre-determined design criterion or that have stylistic guidelines. The abundance of raw material at the quarry, combined with the likely relative ease with which bend breaks could be formed (assuming natural boulders and cobbles had already been broken into) enable a toolkit to be fashioned at low cost in terms of the energy required to produce it.
Moreover, the proximity to the river as a potential resource for subsistence acquisition could have enabled visits to the quarry for raw material acquisition and tool production to be also be embedded in the task of searching for other resources of necessity.

The discovery of large quantities of utilized and modified bend breaks at Topper and recovered in close proximity to the quarry implies that these tools were also likely used as part of a generalized forager adaptation for seasonal onsite task-related activities associated with a riverine subsistence strategy. The area would have supplied a variety of plant, aquatic and raw material resources essential for survival. The results of the microwear analysis suggest that bend break tools were possibly used in the working of medium to hard materials such as bone, wood, or hide which could have subsequently served in the production of tools incorporated into the riverine adaptation. Moreover, the relatively high artifact diversity found onsite consisting of scrapers, utilized flakes, bend breaks, choppers, and core tools implies that the site was integral to multiple as opposed to a relatively narrow range of tasks and could reflect repeated if not seasonal use.

The prospect of chipped stone tools in contexts that predate the Last Glacial Maximum in North America is intriguing. If the lithic assemblages from the pre Clovis contexts at Topper are the product of human agency, what do these results mean in terms of human behavior and the organization of lithic technology in the region and compared with other regions during this period? Although classic bifaces were not a part of the pre Clovis toolkit at Topper, the bend break assemblage at the site is unique and unlike any known pre Clovis lithic assemblage from the eastern U.S., with the possible exception of the Debra L. Friedkin Site.

Unlike Topper, bifaces have been recovered from contexts that underlie Clovis deposits at other early sites such as Meadowcroft Rockshelter, Pennsylvania, and Cactus Hill, Virginia.
At the Debra L. Friedkin Site in Texas, the Buttermilk Creek complex has yielded 15,528 stone artifacts below the Clovis deposits consisting of at least 12 bifaces, 23 modified tools, and three radial breaks among the macro-artifact category. In addition to these items, Wiederhold and Pevny (2014:113) note that a compelling number of artifacts from the pre Clovis assemblage at Debra L. Friedkin are bend breaks, although the authors do not cite what percentage of the assemblage this artifact category reflects. The presence of unfluted bifaces, blade production and core reduction from deposits underlying Clovis at the site has been used in support of the interpretation that Clovis technologies could have evolved from the Buttermilk Creek Complex. However, at Friedkin and many other eastern Pre Clovis sites, the stratigraphic separation between the Clovis and presumably older components is minor in comparison with Topper, leading some critics to question whether the older bifaces observed in pre Clovis contexts are actually the byproduct of vertical displacement or trampling, whether artifacts have drifted downward through the sedimentary deposits, and to what extent the presumably older assemblages significantly differ from Clovis assemblages at all (Morrow et al. 2012). Given these findings, some have argued that the best evidence for legitimate sites of pre Clovis age should lack close associations of cultural components or even evidence of overlying cultural deposits at all (Fiedel 2013). The absence of diagnostic material culture from pre Clovis deposits at Topper, yet still stratigraphically separated from known cultural horizons by a significant amount of comparatively sterile deposits is suggestive of the human use of the site for stone tool production, albeit incorporating technologies distinct from Clovis and post Clovis populations.
CHAPTER XIII
CONCLUSION

This study was designed to examine the presumed pre Clovis assemblage at the Topper Site and to explore potential ways by which it could have formed. Do the lithic deposits that have been recovered below the post Clovis Holocene and Clovis deposits at Topper have attributes that are consistent with human agency and if so are they in stratigraphically discrete, unaltered contexts? This study also has sought to determine if the attributes found on items produced under natural conditions are similar to or different from the attributes common of lithic reductive technologies, and if so, is it possible to distinguish between the two?

Based on the combined lithic analyses, the source of the pre Clovis deposits at Topper has been reconstructed. Evidence from this study supports King’s (2011) findings and demonstrates a human origin for the pre Clovis conchoidal flake assemblage at the site. However, this assemblage likely resulted from flake core and flake tool manufacture as opposed to biface manufacture and furthermore does not reflect bioturbation as an agent responsible for deposition. The assemblage is at minimum 14,000 BP and possibly much older.

The bend break assemblage from the Lower Pleistocene Sands and Upper Pleistocene Terrace at Topper are also considered products of human agency based on the presence of specific technological attributes (compression rings, lips), retouch modification, and lack of differentially weathered scars. By contrast, the analysis could not confirm that items classified as bend breaks from the Lower Pleistocene Terrace were also part of the same lithic reductive technology. The comparatively small size of these items, low Index of Modification values, and microwear patterns consistent with natural processes imply that humans were most likely not responsible for their formation. Given these findings, at the very least, the Topper bend break
assemblage from the Lower Pleistocene Sands reflects the expedient use of broken chert debris (as opposed to intentional manufacture) by pre Clovis peoples that occupied the site at a time between the period that alluvium was being deposited and prior to the onset of significant colluvial slopewash deposition from the adjacent hillside.

The results of this study have theoretical implications on the timing of human settlement in the Southeast U.S. Three important analytical variables direct the acceptance or refutation of pre Clovis assemblages: 1) Are the presumed artifacts cultural and is the context good; that is, are they in stratigraphically intact deposits below diagnostic Clovis material culture? 2) Is there evidence to support the accuracy of the dating and geochronology? 3) Is our current theory postulating the timing and origins of human settlement of North America correct, traditionally assumed to date not much earlier than 13,500 cal yr B.P? Given these variables, any two conditions can be correct, but logic dictates that they all three cannot be. If we accept that people were not in the region earlier than Clovis, then either issues with the cultural affinity of the lithic assemblage itself or the dating of the site are incorrect. By contrast, if we accept the possibility that people could have occupied or settled the region earlier than Clovis, then issues with dating or artifact legitimacy do not necessarily dictate our interpretations of a site as pre Clovis. If the lithic technology and geochronology at Topper have been interpreted correctly, then it follows that people were occupying the region much earlier than current well accepted colonization models suggest. Lithic assemblages that are composed of items that are not associated with an Upper Paleolithic (biface or blade) technology should not be readily discredited as natural without either considering alternative reductive technologies that could have been implemented in their production or developing experimental programs to verify other means by which they could have formed.
What do the results of this study mean in terms of the pre Clovis lithic technology at the Topper Site? Given what little is known about pre Clovis life-ways, tying these conclusions into inferences about pre Clovis period social systems is speculative, but some hypothetical scenarios may be suggested. The results of this study have important implications for understanding pre Clovis lithic technology and technological organization. If the geochronology and lithic analyses are correct, then prehistoric peoples at Topper had access to and made extensive use of the exposed chert outcrop at Topper by a date that precedes the onset of the Last Glacial Maximum. Due to their long use-life, bifaces are often considered to convey significant social information regarding prehistoric life-ways. The presence of thin bifaces and debitage related to late-stage core and biface reduction from pre Clovis aged sediments at Meadowcroft Rockshelter, Pennsylvania, and at Cactus Hill, Virginia, has been used to infer a curated lithic technology at presumably late pre Clovis sites in the eastern U.S and some scholars have used these findings to advocate pre Clovis technological affinities with subsequent Clovis occupations of the Eastern Atlantic slope. Because fluted bifaces are most commonly associated with the hunting of large game, does their absence from the pre Clovis deposits at Topper indicate that such game were not being actively hunted by the site occupants prior to 20,000 cal yr B.P., or do these findings simply mean that bifaces were produced at Topper, but were being carried offsite for use elsewhere? The results of this study show that while some conchoidal flakes are present from the pre Clovis deposits, there is an absence of broken bifaces and biface thinning flakes, indicating that such tools were likely not being produced there at the time. However, future research may prove otherwise. Based on this evidence, the early occupants at Topper likely did not focus on the same resource procurement activities as the Clovis inhabitants.
Informal lithic technologies can also lead to important information regarding the social and technological conditions that surround lithic production and use. Based on the results of this study, informal chipped lithic technologies, namely flake tools and bend breaks, dominated the pre-Clovis lithic assemblage at Topper. The bend break technology at Topper reflects an expedient toolkit geared toward the acquisition and processing of local resources. Based on toolkit composition and proximity to riverine resources, it is likely that the river served as the primary source of subsistence for pre-Clovis inhabitants at the site. Given the abundance of toolstone at Topper, less time and energy would have been required to produce expedient tools such as bend breaks for the acquisition and processing of locally available resources. Moreover, the proposed function of bend breaks as tools for cutting, scraping, engraving or grooving organic media such as bone, antler, or wood is supported by the microwear analysis. As such one could conclude that bend breaks were multifunctional, and given their extraordinary range of possible uses relative to the ease with which they could be produced onsite, were at the very least a practical component of the toolkit, if not a suitable aid in the means of resource procurement.

Avenues for future research

This dissertation provides a detailed description of the lithic technology of the pre-Clovis assemblage at the Topper Site. While the results of this study offer important evidence regarding the nature of the lithic assemblage at the site, there are a number of areas where future research may provide additional insight about pre-Clovis life-ways in the region and at Topper. Existing colonization models should be evaluated, adjusted, or modified based on the results of empirical test implications and logical coherency. If people were in the southeastern U.S. prior to the onset of the LGM, Topper is likely not the only locale where people stopped and other sites with similar chipped stone tool assemblages should exist. Future archaeological research should
explore the possibility of other regional sites that might corroborate or invalidate the results at Topper. Leigh (2008) suggested that archaeologists should target Pleistocene landscapes such as terraces adjacent to former braided river channels as they are the locations most likely to retain well-preserved pre Clovis sites.

It could benefit future lithic research endeavors to expand the lithic attribute criteria required for the verification of cultural artifacts. If the attributes that are considered diagnostic of human lithic manufacture are limited to the byproducts of a narrow range of reductive technologies (conchoidal flakes resulting from biface manufacture), then the potential exists that the lithic items produced by alternative chipped stone technologies could be misclassified as natural. In other words, if bifaces and their byproducts operate as the minimum lithic criteria needed to be considered a cultural assemblage in North America, then by what objective means would the lithic analysis ever recognize the byproducts of alternative lithic reductive technologies? With regard to lithic attributes, some reductive technologies do not always result in the formation of flakes with striking platforms and bulbs of force. For example, bipolar technologies can result in lithic attributes that might mimic the morphology of natural fractures, yet still maintain specific technological attributes that can be distinguished from natural processes. Compression rings indicative of force application are but one such attribute whereas lips along the break angles of radial and bend break flakes are another. Therefore, by expanding the range of possible attribute criteria to include at minimum compression rings indicative of force application, acknowledging the potential morphological attributes consistent with natural processes, as well as the sedimentological context the assemblage was recovered in, it is possible to evaluate archaeological contexts for the presence of a much broader realm of possible lithic technologies.
The detailed scale of analysis enables informed interpretations about the authenticity of the Topper lithic assemblage, although the data may benefit from comparative analysis with other regional pre Clovis assemblages. Is Topper truly unique in North America, or are there other sites whose assemblage contents might share similarity with Topper? The search for new sites and assemblages of which the dates and lithic technology might compare with the results at Topper might help resolve such issues. The reexamination of previously excavated assemblages for potential evidence of pre Clovis material culture might also be beneficial.

At the site level, a better understanding of the spatial relationship of artifact types from the Upper Pleistocene Terrace at Topper would aid in the interpretation of the use of this area of the site. Enlarging the footprint of this area through additional excavation would allow for better horizontal resolution of the archaeological assemblage. Moreover, such fieldwork might allow for the identification of possible activity areas, which may subsequently be compared with those identified from the overlying Pleistocene Sands and Clovis components. A microwear analysis of a much larger sample of the tool assemblage and with the aid of high-power microscopic equipment will allow more informative explanations regarding the past use or uses of the lithic artifacts. Specifically, studies aimed at verifying the presence or absence and type of residue on lithic tools can be applied to understand tool function, the material being worked, or if the patterns are the result of natural formation processes. The incorporation of experimental use-wear studies may also clarify such issues. Moreover, the recovery and testing of artifacts from pre Clovis contexts for blood protein residue, if present, could shed light on subsistence practices and would aid in the interpretations of the use of specific artifact types. Additional geoarchaeological investigations at Topper would be beneficial to eliminate possible disturbance processes. Such research might offer better insight about the role of fluvial processes on the
Upper Pleistocene Sands and the presence and degree to which bioturbation may or may not have led to vertical displacement of artifacts between the Clovis and Upper Pleistocene Sands.

The discrepancies found in the two dating studies of the Pleistocene Sands need to be resolved. The biggest concern with the Topper geochronology based on the new OSL dates is that the ages obtained for the Pleistocene Sands differ significantly from the dates obtained by the Waters et al. (2009) study. Although present research implies that the deposits are pre Clovis in age, one study suggests a significantly younger date range, whereas more recent dating places the unit’s formation closer in age with the underlying Pleistocene Terrace. Therefore future research should examine additional samples from these units to verify the true age of the deposits. Another useful inquiry would be the effects of longer-term and broader based experimental weathering processes on chert materials, and the development of additional experimental analyses in general. Additional analyses incorporating replication are essential. Such studies would provide a better understanding of the role of the environment in the formation of lithic assemblages, which in turn may aid in the development of more informed interpretations about pre Clovis material culture. More importantly such avenues of research can move us beyond our preconception of pre Clovis peoples as only biface or blade producers and toward a much broader understanding of the reductive technologies practiced by early hunter-gatherer societies in North America.

APPENDIX 1

CULTURE HISTORY
Research has identified evidence of cultural activity at the Topper Site that spans at least 13,500 years of human history in the region. This appendix offers a Culture history for the Coastal Plain of the Middle Savannah River Valley and provides a framework for interpreting the cultural sequence at the site. I begin with a discussion of the Paleoindian and Archaic periods, and conclude with an overview of the Woodland and Mississippian periods. A summary is provided that describes the major cultural trends, settlement subsistence strategies, and types of artifacts that are considered diagnostic of each period. The goal of the overview is to provide a setting in which settlement subsistence and tool-stone procurement activities at Topper could have occurred. Moreover, lithic materials from Paleoindian and all later periods in prehistory occur in the upper 1.5m of deposits at Topper, and due to cultural or natural transformation processes, the potential exists that these items may be the source of the materials identified in the Pre-Clovis deposits at the site. Therefore an understanding of the material culture that comprises these deposits is essential to any interpretation of a possible pre Clovis occupation at the site. Examples of artifacts from potential pre Clovis sites in the Eastern U.S. are presented in Figure A1–1. Sassaman et al.1990 have reviewed the archaeological evidence for prehistoric occupation of the Savannah River Valley near Topper. At the broadest scale, culture chronology for the region may be divided into four primary periods; Paleoindian, Archaic, Woodland and Mississippian. The following chronology forms the basis from which the Culture history at Topper is defined. A complete chronology is provided in Figures A1-2-and A1-3 as a reference for the specific age of cultural groups discussed in the text and their temporal designations.

**Paleoindian Period**

Paleoindians in North America have traditionally been portrayed as highly mobile big game hunters who, after migrating from Northeast Asia sometime after the Last Glacial
Maximum (LGM) 21,000 cal yr BP, followed and specialized in the procurement of Pleistocene megafauna as they migrated across the North American continent. Known as Clovis, based on the nearby town in New Mexico where diagnostic projectile points were recovered in associated contexts with extinct megafauna, these Late Pleistocene Paleoindian hunters have long been considered by many to be the oldest well-documented culture complex to inhabit North America.

The first widespread human occupation of the Southeast occurred approximately 13,500 cal yr BP when Clovis sites and assemblages, characterized by distinctive fluted projectile point technologies appeared rather abruptly. Clovis and other early cultures to inhabit North America at the terminal Pleistocene have traditionally been referred to as Paleoindian. This term was originally coined by Frank H. H. Roberts in 1940 as a way to define the first cultures to inhabit North America (Anderson and Sassaman 2012:36). Paleoindian cultures were defined as those that predate 13,500 cal yr BP and refer to settlement subsistence strategies that place emphasis on high mobility, the specialization in the procurement of large game, and that do not yet rely on agriculture or horticulture. Until the late 20th century, Clovis peoples were assumed to have entered the continent no earlier than 14,000 cal B.P. based on the discovery and subsequent dating of Pleistocene age mammals found in direct association with diagnostic fluted projectile points. “Traditional perspectives” for the initial occupation of the southeast U.S. have peoples entering the region from the north and west, predominantly along the major river drainages that flow into the area (Anderson and Sassaman 2012:36). However the recent discovery of sites containing potential human artifacts in contexts that predate Clovis across the Southeastern U.S. have extended the accepted timing for which peoples are assumed to have initially entered the region. Today, it is widely accepted that the first peoples to occupy the Southeastern U.S. likely
arrived at some point just after the last glacial maximum (21,000 cal yr BP) (Anderson and Sassaman 2012:36).

Regardless of how or when they arrived, the intentional rapid movement of colonizing populations into new areas of continental North America during the Late Pleistocene has been attributed to a combination of factors including the widespread availability of favorable resource patches in virgin environments, the ease of procuring naïve prey, and the lack of competition from preexisting human populations (Caldwell 1958; Griffin 1952; Wormington 1957). More recent research based on new archaeological data has indicated that Paleoindians in Eastern North America likely practiced what has been described as an opportunistic subsistence strategy that focused on the exploitation of a diverse range of biotic resources including small mammals, fish, and plant resources in addition to large mammals (Meltzer and Smith 1986; Meltzer 1988; Anderson 1990, 2013; Dincauze 1993; Ferring 2001; Haynes and Huckell 2007; Hollenbach 2007; Meltzer 1988, 1993; Speth et al. 2013; Walker and Driskell 2007). Such a diet supports a generalist subsistence strategy. While the reliance on large game to support subsistence needs is probable, evidence of such exploitation in the Southeast is sparse owing to poor preservation in many areas.

Paleoindian research in the Southeast often centers on the development and testing of models that attempt to account for some aspect of technological organization, population movement or settlement subsistence strategies relative to the distribution of material resources across the landscape (Anderson 1990; Anderson and Sassaman 1996; Daniel 1996 Anderson and Hanson 1988; Gardner 1977; Goodyear 1989; Kelly and Todd 1988; Miller and Smallwood 2009). Models developed to account for the distribution of Paleoindian sites often consider variables such as distance water, tool-stone, plants, physiography, or some combination of the
above (Anderson 1990, 2013; Daniel 2001; Miller and Smallwood 2009; Hollenbach 2007). These models form the basis of how scholars interpret the archaeological record in the region.

One of the earliest settlement models was developed by William Gardner. Based upon excavation at prehistoric quarry sites in Northern Virginia, Gardner developed the Flint Run Lithic Determinism model which proposes that Paleoindian settlement was seasonally tethered to resources such as quarries. The constraints brought about by the reliance on raw material sources for the production of tools is seen as a causal mechanism for reduced mobility (Anderson and Sassaman 1996:23; Gardner 1974, 1977, 1983). According to the model, Paleoindians set up base camps near fixed predictable resource rich places on the landscape such as quarries where they could return to as needed for tool stone acquisition during hunting excursions or forays. Such familiar points on the landscape may also have been useful as areas of aggregation where groups could have come together for the exchange of goods. Gardner’s model stresses a low degree of population mobility, as opposed to high movement of populations across vast areas of the landscape (Daniel and Wisenbaker 1987). The model is found to work best where lithic resources are limited, such as the South Atlantic Coastal Plain, but in physiographic regions of abundant lithic materials, there would be little need to justify a return to the same source.

During the 1970’s Albert C. Goodyear (1979, 1989) developed a settlement model that places emphasis on the quality of raw material for the manufacture of stone tools. Known as the “Cryptocrystalline Hypothesis” Goodyear suggested that the placement of high quality cryptocrystalline chert sources distributed across the landscape played a significant role in population settlement subsistence patterns. The location of raw material is stable, and therefore, predictable; the occurrence and availability of food is not (Goodyear 1989). Before people could manufacture stone tools, they needed to know where on the landscape to obtain the suitable and
necessary raw materials for their production. Because it was not always possible to attract the large game to sources of raw material, an adaptive strategy was in need that would allow for sufficient production and transport of necessary resources, and at least cost, to support daily subsistence needs. Although Goodyear supported Gardner’s claim that raw material access played a critical role in determining the settlement patterns of Paleoindians, he contended that higher residential mobility was probable, and that lithic raw material procurement was an “embedded” practice in the settlement subsistence strategies of these peoples. In the absence of being bound to a specific chert source, Paleoindians, according to Goodyear, would require a reliable means of conserving and transporting tool-stone across the landscape to areas of need. One way to accomplish this is through the selection of materials of high quality for the production of a curated tool technology (Anderson and Sassaman 1996:26; Goodyear 1989). Biface technologies fit this concept well as they are portable, efficient and versatile tool types that would have allowed Paleoindians to adapt to a variety of environments as they moved rapidly across the landscape (Kelly and Todd 1988).

Anderson and Hanson (1988) have argued that in the South Atlantic Coastal Plain, hunter-gatherers may have organized their settlement subsistence systems along major river drainages that were oriented to and from the coast. These drainages would have supported resource rich environments that could have been readily exploited in support of dietary needs. Daniel (1998) and later Miller and Smallwood (2009) have evaluated this model in detail. Miller and Smallwood have found that areas where major rivers and physiographic boundaries intersect are good predictors of Clovis biface density, and where knappable chert was likely present (Miller and Smallwood 2009). The authors argue these areas would have also served as suitable locales for seasonal aggregations of multiple Paleoindian bands (Miller and Smallwood 2009).
Anderson (1990) has proposed that during the colonization process, Paleoindian groups settled ecologically rich areas of the landscape such as river valleys in order to familiarize themselves with the landscape for a brief period prior to expanding their population size and radiating into adjacent areas (Anderson 1990). These ecologically rich places are referred to as staging areas (Anderson 1990), and are identified on the landscape where dense concentrations of fluted points tend to occur. The Tennessee and Savannah River valleys are considered to be prime examples of staging areas. Conventional colonization models have initial Paleoindians populations filling into staging areas in the Midwest, and eventually spreading technological adaptations to the south and east (Anderson 1990). This implies directionality in the settlement process (Smallwood 2012). Based on the distribution of known Clovis points and raw material sources in the Eastern U.S, a number of other locales fit the description of Anderson’s “staging area” model. These areas include the gulf coast of Florida and Texas, and the Delmarva Pensinsula and Nottoway River Valley of Virginia. Moreover, increasing evidence of archaeological sites relating to the Paleoindian period in the Savannah River Valley is indication that this region may also have served as one of Anderson’s “staging areas” (Anderson 1990). The hypothesized directionality of initial colonization implies that these areas would have been settled later than regions to the west. However, a numner of Clovis sites from these regions also have earlier components that are reported to date earlier than 14,000 cal yr BP (Anderson 2005; Goodyear 2005; McAvoy and McAvoy 1997; Lowery et al. 2010). These discoveries challenge the proposition that Clovis developed outside Eastern North America, and are evidence for a Late Glacial Maximum occupation of the region. In the Savannah River Valley, the Paleoindian period can be broken into three distinct sub periods referred to as Early, Middle and Late; with Early Paleoindian comprising the pre Clovis culture (Anderson and Sassaman 2012, Anderson et
Each sub period is characterized based largely on changes in lithic technological organization possibly resulting from fluctuations in climate. In the sections that follow, I provide a brief overview of each of these sub periods.

**Early Paleoindian (>13,500 cal yr BP)**

Archaeological evidence for human occupations of the Southeast prior to 13,500 cal yr B.P. is relatively sparse, with only a handful of sites identified to date. (Webb 2006; Dunbar 2006; Goodyear 2005; Lowery 2002; McAvoy and McAvoy 1997; Waters et al. 2011) (Figure 2-2). Most sites reported as pre Clovis in the Southeast fall within the Early Paleoindian period, and typically consist of lithic assemblages containing materials that are informal in nature, and are not diagnostic to any known culture complex thus making temporal designation difficult when items are recovered in questionable contexts. Because of the general scarcity of material culture attributed to pre-Clovis peoples, population densities are assumed to have been low during this time. Based on the relatively small sample size of site and assemblage data available for comparative analyses, archaeologists have “little idea how pre Clovis groups were organized” with regard to settlement subsistence strategies and the organization of lithic technology in the Southeast (Anderson and Sassaman 2012:45). However, a number of archaeological sites in Eastern North America demonstrate evidence of pre Clovis occupation. At Page Ladson, a submerged Paleoindian site located adjacent to the Aucilla River in North Florida, a mastodon tusk with reported cut marks has been found in association with small flakes and cobble like fragments. At the Cactus Hill Site in Virginia, Clovis artifacts consisting of bifaces and blades have been recovered from sandy deposits that overlay an older assemblage consisting of blades and triangular bifaces referred to as Miller points (McAvoy and McAvoy 1997). These points are morphologically similar to examples that have been identified from the pre Clovis contexts at the
Meadowcroft Rockshelter Site in Pennsylvania. The older component at Cactus Hill may date between 16-18k cal BP (McAvoy and McAvoy 1997).

A number of potential pre Clovis sites have been reported from the Delmarva Peninsula, and include Miles Point, Paw Paw Cove, Crane Point and Oyster Cove; and Cinmar (Lowery et al. 2010). At The Miles Point Site in Maryland, Lowery et al. (2010) have reported the discovery of buried prehistoric materials along a shoreline associated with pre Clovis features (Lowery et al 2010). Subsurface investigations at the site revealed a small projectile point, blade like flakes, polyhedral blade and bipolar cores, and utilized pebbles from eroded shoreline deposits that date between 27,940+/-1,635 BP to 29,485+/-1,720 BP using the multiple aliquot OSL technique (Lowery et al. 2010:3-7). The morphological similarity between points found at Cactus Hill and those recovered from sites on the Delmarva Peninsula (Miles Point, Paw Paw Cove, Crane Point, and Oyster Cove) are considered by some to indicate a possible pre Clovis lithic complex for this region.

At the Cinmar site, situated on the outer continental shelf of southern Virginia, a large bifacially flaked rhyolite knife dredged from 70m beneath the water surface by a scallop trawler. The point was recovered along with the remains of a mastodon skull, tusk section, and teeth fragments (Lowery 2014:75; Stanford and Bradley 2012). The point is described as laurel leaf in form and resembles types characteristic of the Solutrean culture of Europe. Subsequent dating of the mastodon skeletal materials returned an age of 22,760 ± 90 $^{14}$C yr BP which is “consistent with the LGM sea level data that suggests the animal perished on the outer continental shelf when sea levels were much lower during the initial phases of the LGM (Lowery 2014:82). Examination of the XRF spectra of the biface demonstrates that it is similar to the spectra found in rhyolite outcrops near White Mountain Pennsylvania (Lowery 2014).
specimen recovered at Cinmar. Along with the small triangular bifaces (Miller points) found at presumed pre Clovis deposits at Cactus Hill, Virginia and at Meadowcroft Rockshelter, the large bifaces recovered along the Mid Atlantic coast may reflect a second point form diagnostic to the Early Paleoindian sub period. Figure A1-1 presents a sample of Early Paleoindian biface forms recovered from the Middle Atlantic. As of the 2012 field season, bifaces are absent from pre Clovis Pleistocene Terrace deposits at Topper, although a very rudimentary “crude” biface was recovered from the Upper Pleistocene Sands. Near Franklin, Tennessee, an assemblage consisting of ten stone tools and 24 flakes was recovered in direct association with the remains of mastodon and other well preserved Pleistocene age fauna (Deter-Wolf et el. 2011:147). Known as the Coats Hines Site the results of radiocarbon dating of materials from the top of the artifact bearing deposits in 2010 produced a date of 12,050 ± 60 14C yr BP making Coates Hines one of the oldest human occupation sites in the Mid-South. Coates Hines is interesting in that the site lacks evidence of any overlying cultural deposits above the presumed pre Clovis level. As such, this discovery nullifies any questions regarding bioturbation from Holocene cultural contexts.

Perhaps the most precisely dated pre-Clovis site in North America, the Debra L. Friedkin Site (DLF) in Texas has revealed a flake and biface assemblage that dates between 15,000-16,000 cal yr BP (Waters et al. 2011). This assemblage lies approximately 2cm beneath Clovis deposits, and is situated adjacent to a small tributary. Excavations at DLF have revealed close to 16,800 artifacts from an archaeological deposit named the Buttermilk Creek Complex (Waters et al., 2011a; Wiederhold and Pevny:2014). Apart from the biface and flake assemblage, a possible artifact assemblage consisting of bend break and “radial obtuse angle tools” were identified from pre Clovis contexts (Crabtree 1977; Wiederhold and Pevny 2014). According to Weiderhold and Pevny (2014), of the nearly 16,800 lithic items recovered from the DLF complex, a “compelling
number of bend-break and radially fractured fakes were identified from the assemblage. A technological examination of a sample of the bend and radial break artifacts from DLF and subsequent comparison with experimentally produced specimens found that the two assemblages are comparable (Jennings 2011). Moreover, based on the experimental study, there are substantial differences between the attributes found on flakes broken during biface production, flakes that were experimentally trampled, and flakes that were intentionally produced (Jennings 2011). A microscopic examination of a sample of bend breaks from site showed that the margins formed by the “snap fractures exhibit polish and striations” that were likely produced by “particles of the tool and the worked material” (Weiderhold and Pevny 2014:113-114). These findings imply that bend breaks from the assemblage at DLF were not only fractured deliberately, but were also used (Weiderhold and Pevny).

To date, Topper and DLF the only two North American sites where bend break flakes have been reported from pre Clovis contexts. Although the results at DLF indicate that these artifacts were intentionally produced for use as tools, similar analyses must be undertaken on the items recovered at Topper to validate or disprove whether they too are a product of human agency. As such, the current study provides a comparison of the Topper pre Clovis lithic assemblage with other possible pre Clovis assemblages from the continent. Excluding Topper, and the presence of flakes well below the Clovis deposits at the Ricker’s bottom site, evidence for pre Clovis occupation of the Savannah River Valley has not been demonstrated (Anderson). Due in part to the infrequent occurrence of legitimate pre Clovis sites, questionable artifact assemblages, and dissimilar toolkit composition, few models of Early Paleoindian settlement subsistence adaptations have been advanced. Anderson (2013) has proposed that early coastal colonizing populations could have accessed major river drainages to the Eastern U.S. via the
Colorado River from the Baja Peninsula. Upon reaching the Gulf of Mexico, populations could have followed the coast north and into Eastern North America (Anderson 2013). Coastal landscapes are one form of “least cost pathway” for population movement. If groups were utilizing such ecotones for resource procurement, why move to the interior if essential resources could be acquired in already familiar landscapes? Recent discoveries of Clovis and potentially earlier bifaces (Lowery 2012; Stanford 2014) from coastal and submerged landscapes have provided important evidence regarding Early Paleoindian subsistence adaptations. Research efforts are beginning to focus on now submerged landscapes for evidence of Late Pleistocene Sites. If we know the rate of sea level rise, then it is possible to predict the timing at which some areas of former landscapes could have been occupied. Figure A1-5 presents a map showing the extent of sea level rise along the Eastern U.S. for select time periods. In the Eastern U.S., an examination of Clovis point data from the Southern Atlantic Coastal Plain by the author has found that the highest densities of Clovis points in coastal areas occur where major rivers intersect broad coastal zones as opposed to narrow coastlines, and that river drainages associated with adjacent outcrops of high quality tool stone have the greatest densities of fluted points. The results of this project (Sain 2013) are presented in Table A1-1, and Figures A1–4 through A1–10. More importantly, the results of this study could have implications regarding the settlement subsistence strategies practiced by potential pre Clovis populations inhabiting the region, including Topper, and allow for the development of hypothetical models of pre Clovis settlement subsistence. Approximately 14,000 B.P. marine transgression associated with MWP1A resulted in the submergence of areas of the Atlantic continental shelf. If pre Clovis groups occupied coastal regions during this period, then the expectation favors eventual inland migration as a result of marine transgression, and the rapid breaching low lying areas. Relocation to inland
regions would have initially focused on the major river drainages adjacent to broad coastal zones. Rivers with relatively low discharge rates and gently sloping gradients would have initially been favored. The Savannah River is one such drainage that fits this model. The discovery of high quality raw material sources along inland drainages via pre Clovis excursions would have facilitated greater mobility to and from the coast.

A number of these locales may have initially been utilized by Pre Clovis groups for the manufacture of a mixed riverine /coastal toolkit. If the Topper Site does in fact contain evidence of chipped stone tools from the deposits that underlie Clovis, then the nature of the assemblage could inform about settlement subsistence practices. The proposed expedient microlithic flake tools recovered from the pre Clovis deposits at Topper could have been suitable scraping or filleting tools whereas bend break/burin and radial break artifacts could have been procured or manufactured to groove, incise, or shape wood or bone. Once settled into inland locales, Paleoindian groups would have adjusted their toolkits accordingly, in response to changes in resource abundance and distribution. By 13,300 cal yr B.P., sites would have been situated primarily at the intersection of major drainages and high quality raw material sources. Increased sea level rise during MWP1B would have left submerged the Clovis era shoreline resulting in additional population retreat from coastal areas. After this time, coastal resources would have played a less significant role in the settlement subsistence systems of prehistoric peoples occupying the Atlantic slope, lasting until the Early Archaic. The early lithic assemblages documented at sites such as Topper, Cactus Hill and Miles Point may have served as very early staging areas where populations aggregated and from which people later radiated out over the surrounding area forming regional macro bands (e.g. Anderson Hanson 1988).
Middle Paleoindian (13,250 - 12,850 cal yr B.P.)

The Middle Paleoindian Period represents a time of rapid population growth throughout North America, but is most visibly apparent in the Eastern Woodlands where high numbers of readily identifiable fluted Clovis projectile points appear suddenly on the landscape (Anderson and Sassaman 2012:40). When not recovered from deeply buried stratified sites, Clovis points occur as isolated finds over the landscape. Anderson and colleagues have complied point data from individual state recording projects, documenting nearly 3,500 Clovis points east of the Mississippi and south of Virginia (Anderson et al. 2012:48). Interesting patterns are found when Middle Paleoindian point distributions are plotted relative to physiographic boundaries. In the Mid Atlantic, Lowery et al. have used fluted projectile point estimates for the Delmarva Peninsula and from published reports from the Carolinas to suggest that greater point densities are found along broad coastal zones than are recovered where coastal zones are narrow (Lowery et al. 2012). Accordingly, the wide, gently sloping coastal settings of the Delmarva would have promoted increased marine productivity during the late glacial period, thus explaining the greater occurrence of fluted points from this region. In the Southeast U.S., Middle Paleoindian point densities are typically highest in the upland interior and Piedmont as opposed to the Coastal Plain (see O’Donoughue 2007; Smallwood et al. 2015). By the Late Paleoindian period, there is a shift to the west in the distribution of post Clovis point varieties compared to Clovis forms possibly indicating a population reorganization as climate changed with the onset of the Younger Dryas cold interval (12,850 cal yr BP) (Miller and Gingerich 2013; Anderson et al. 2013; Smallwood 2015). This shift is evident when one examines the distribution of Middle and Late Paleoindian points across the region (Figure A1-7, A1-8). Smallwood (2015 has made similar findings from the analysis of fluted point distributions from Georgia.
The Middle Paleoindian period in the Savannah River Valley begins with the first widespread appearance of the Clovis culture throughout the area and is marked by the occurrence of lanceolate fluted projectile points, biface preforms, and blades recovered from stratified buried contexts and as surface finds. Clovis points are the earliest form of diagnostic artifact in the region and are identified based on the presence of a flute created by the removal of a channel flake removed from the base of the point. Although the recovery of Clovis points from surface contexts is a frequent occurrence throughout the Savannah River Valley, the number of documented subsurface, stratified Clovis sites in the immediate area is rare. Sites where Clovis artifacts have been recovered in buried contexts in the middle Coastal Plain include Topper (38AL23), and Big Pine Tree (38AL145) in Allendale County, and from the rim of Flamingo Bay (38AK 468), a Carolina bay on the U.S. Department of Energy’s Savannah River Site in Aiken County (Goodyear 2005; Goodyear and Steffy 2003; Miller 2007, 2010; Moore 2012; Smallwood 2010, 2011; Smallwood et al. 2013). A single Clovis point was recovered from the Rucker’s Bottom Site in the Piedmont. Complete, finished Clovis points are rare at these sites. Smallwood (2010, 20012) has found that biface preforms recovered from the Topper Site are variable in size due to constraints in raw material package sizes, and that “Clovis populations had to adjust production strategies to suit resource conditions” (Smallwood 2010:2424). In addition to the biface preforms and points, prismatic blades have also been identified from the Clovis contexts at these sites, and provide evidence that hunter gatherers of the period were practicing other activities apart from only hunting (Steffy and Goodyear 2006; Sain 2010a, 2010b; Sain 2011; Sain and Goodyear 2012). The relative absence of modified blades at Topper compared with the abundance of blanks could imply that groups were producing these artifacts at the quarry only to be used away from the immediate vicinity (Sain 2012). However, Weidman has
found evidence that blade technology is more frequent at site 38AL228 (a nearby quarry related lithic manufacture site) than at Topper (Weidman 2013). These findings imply that “high quality chert nodules or prepared blade cores were being selectively imported into the site for blade manufacture” (Weidman 2013:1).

Late Paleoindian (12,850 - 11,700 cal yr B.P.)

The Late Paleoindian period is marked by increasing variability in the distribution of projectile point types across Southeast. The Late Paleoindian period begins with the appearance of Cumberland and Redstone points, which are thought to date to the Younger Dryas (YD) period sometime after 12,900 cal yr BP. These point varieties are fully fluted and might reflect adaptive behaviors relating to changes in faunal distributions with the onset of cooler climate. Over time, a number fluted point varieties have been identified at Paleoindian sites throughout the Southeast, as well as the discovery of bone and ivory tools in Florida. The great variability in Paleoindian point forms in the Southeastern region has been used by some (Anderson and Gillam 2000; Anderson and Faught 1998; Mason 1962) to suggest that the Clovis technology (13,200-12,900 cal yr BP) may have arisen in the southeast and Mid-south, and subsequently spread out into adjacent regions over time. After the onset of the YD (ca. 12,850 cal BP), there appears to be a shift in the distributional range of post Clovis point varieties to interior locales (Miller and Gingerich 2013, Anderson et al. 2013; Smallwood et al. 2015). Furthermore, some have argued that this period witnessed a population decline owing to the elevated ratio (4:1) of Clovis points to Late Paleoindian varieties such as Redstone (Goodyear 2006; Anderson et al. 2010, 2011). If the environment was less productive during the YD than in was in the preceding millennia, then logic follows that Paleoindian populations may have come together in central locales in an effort to pool resources in times of necessity. During the terminal YD, the occurrence of waisted and
un-fluted Suwanee and Simpson points increase in abundance across much of Florida and southern Georgia as do a variety of Clovis variants (Anderson et al.1996:11; Anderson et al. 2010; Smallwood et al. 2015). Moreover, increases in the abundance and distribution of other point forms such as Quad and Beaver Lake found in the Mid-South have frequently been used to suggest an increase in population as climate was once again becoming more moderate by the terminal Pleistocene.

The later part of the YD, is characterized by the appearance and widespread distribution of Dalton points across the region. The emergence of the Dalton Culture is considered by some to reflect a population reorganization in response to changing settlement subsistence practices (Morse 1971, 1973; Sassaman 2010:39). Dalton points vary significantly in morphology across the Southeast. The discovery of large examples that display high workmanship associated with a prehistoric cemetery at the Sloan site in Northeast Arkansas is a an early example of ceremonialism and increased social complexity (Walthall and Koldehoff 1998). In the Savannah River Valley, Dalton points differ from earlier fluted predecessors in that they are smaller, relatively thin, and often exhibit pronounced resharpening that is attributed to changes in the types of game that are being hunted (Goodyear 1974; Morse 1973). These findings further attests to the implication that changes in climate and thus resource distribution may have influenced to some extent changes in lithic technology (Anderson 1990, 2013; Morse 1971, 1973, 1974; Goodyear 2006; Meeks and Anderson 2012). The end of the YD marked the close of the Paleoindian period, and is characterized by amelioration in climate leading to major shifts in vegetation communities throughout the Southeast at the onset of the Holocene. Such changes may have contributed to extinction of the large mammals that thrived during the Pleistocene, with some reports suggesting the loss of as many as 35 genera (Grayson 1991:195)
Archaic Period (11,700 – 3,200 Cal B.P)

In 1932 William A. Ritchie (1932) coined the term Archaic to reflect cultures who subsist primarily by way of hunting and gathering, and that lack agriculture, horticulture, and the development of ceramics (Anderson and Sassaman 2012). In defining the Archaic culture Ritchie explained that stone tool assemblages were being recovered in contexts that were preceramic and that predated the Woodland period (Ritchie 1932a; 1932b; Emerson and McElrath 2001:25). However, in the following decades this view of the Archaic largely changed as archaeological evidence began to show that certain characteristics of the social complexity of Archaic groups that had been attributed to later periods actually had their origins much earlier. Unlike Paleoindians, Archaic peoples subsisted to a greater extent on smaller game of the Eastern woodlands after the extinction of Late Pleistocene mega-fauna. The initial Archaic can be distinguished from earlier Paleoindian cultures based on a change in lithic technology away from the production of large lanceolate projectile points, and to an emphasis on smaller corner and side notched varieties. Although evidence suggests that Early Archaic groups were less mobile than the Paleoindian peoples before them, early to mid-20th century research favored a forager mode of resource procurement whereby groups primarily practiced residential mobility. Overtime, Archaic peoples tend to exhibit increased organizational complexity (Anderson and Sassaman 1996).

Unlike Richie, not all archaeologists were initially willing to accept the term ‘Archaic’. James B. Griffin (1946) suggested the term was too broad to account for all cultures that represent this period across all regions, and therefore proposed that archaeologists refrain from using the term (Griffin 1946:42; Willey and Phillips 1958). Griffin (1946:42-43) even declined to incorporate the term Archaic into use as he considered the Lamoka type assemblages
“represented a culture that was too primitive and much too late” to be defined as Archaic (Emerson and McElrath 2001:25). Griffin (1952, 1967) ultimately accepted the term Archaic and developed a two-fold sequence, (Early and Late), to account for differences in Archaic material culture over time. Although ceramics and agriculture were absent from both sub periods, the Late Archaic, according to Griffin, was distinguished from the former by the addition of ground stone and steatite vessels as well as the introduction of objects manufactured from bone and shell bone and shell into the technological repertoire of the prehistoric inhabitants (Griffin 1952:355). Furthermore people became organized into small bands of approximately 20-30 people that practiced seasonal mobility systems consisting of well structured groups that moved in distinct territories in search of food resources” (Ward and Davis 1999:8). Whereas status might be achieved, social complexity was lacking. Since the 1950’s Griffin’s model has been refined as new data has become come available through archaeological surveys and excavations. Since this time, archaeologists have now come to recognize a third period (Middle Archaic) that distinguishes various aspects of social complexity throughout the Southeast. Anderson and Sassaman (Anderson and Sassaman 2012:71) have suggested that the transition from one cultural period to another during the Archaic is thought to coincide with “broad climate trends of the post glacial” and subsequent changes in resource structure across the lower Southeast.

The following section provides a brief summary for each cultural sub-period of the Archaic in the Savannah River Valley. A description is given for the primary technological, social and cultural trends that are considered diagnostic to each sub period. At Topper lithic materials from probable Early, Middle, and Late Archaic sequence have been identified from the excavated deposits at the site, and therefore an overview of each sub-period is essential to place the material culture into spatial temporal context. Moreover, An understanding of the types of
chipped stone tools and debitage produced by Archaic peoples can serve as a means of comparison with the tools and lithic byproducts recovered from deposits of unknown origin and may well help establish whether or not post depositional processes have been active at Topper in the past.

**Early Archaic (11,700 - 8900 cal yr B.P)**

The Early Archaic period in the Savannah River Valley culture sequence coincides with a “cool but stabilized” climate interval that separates the Younger Dryas and the much warmer Mid Holocene (Anderson 2001; Anderson and Sassaman 2004; McElrath et al. 2001). Changes in lithic technology during the early Archaic coincide with an increase in global temperature at the onset of the Holocene, and an increase in the distribution of oak and hickory hardwood forests throughout the Lower Southeast (Anderson and Sassaman 2012). The Early Archaic period is defined based on radiocarbon dates, but more substantially on the notable series of deeply buried, stratified “river bank sites formed largely by a number of technological trends occur during the Early Archaic. There is a change as well as increased diversity in projectile point morphology that is considered to reflect adaptations taken in response to regional environmental changes throughout the Southeast. Diagnostic projectile point forms that characterize the Early Archaic include the side-notched, corner-notched, and bifurcate projectile points (Chapman 1975, 1985; Coe 1964; Michie 1966). The first Archaic points appear 11,800 cal yr BP as side notched forms and spread rapidly across the Southeast. The earliest diagnostic forms in the Savannah River Valley are side notched varieties such as the Taylor point (10,000-9000 $^{14}$C yr BP) and are thought to have replaced the Dalton points of the Late Paleoindian period. Coe (1964) recognized three Dalton varieties; the Hardaway-Dalton, Hardaway Side Notched, and Hardaway Blade points based on examples recovered from excavations at the
Hardaway site in North Carolina. Coe hypothesized that each type represents a sequential variant occurring over a fairly prolonged period preceding the onset of the Early Archaic (Coe 1964). Hardaway Dalton (10,500-9800 \(^{14}\text{C} \text{ yr BP}\)) and Hardaway side notched points distinguishes between the Late Paleoindian and Early Archaic periods.

Taylor points and Dalton points are found extensively throughout the Savannah River Valley although they do not always occur in stratified contexts at the same site. Dalton points have been found in high quantities at the Big Pine Tree (n=24) and Charles Sites along the Savannah River but are largely absent at Topper (n=1) (Goodyear et al. 2007). In contrast, Topper exhibits a well-defined Taylor occupation represented by no fewer than seven points recovered from a 10-15cm deposit on the floodplain terrace at the site. These patterns suggest that hunter gatherers of the region may not have always been accessing the same quarry sites with the same intensity through time. However, many of the points that date to the Early Archaic exhibit extensive reworking suggesting they were used as “multipurpose hunting/butchering tools” (Anderson and Sassaman 2012:57). Other side notched point varieties of the Southeast include Taylor, Kessell, Bolen, and Big Sandy related point types (Ellis 1991). After side notched points, and by 10,800 cal yr BP, corner notched varieties such as Palmer and Kirk increase in abundance throughout the region. Kirk points were originally denied by Coe (1964:56-83) based on his work at the Hardaway Site in North Carolina. Points produced during later parts of this sequence are occasionally serrated.

Following the side notched horizon, bifurcate points (10,000 to 8700 cal yr B.P.) occur in limited numbers throughout the area, and include types such as MacCorkle, St. Albans, LeCroy, and Kanawha (Broyles 1966, 1971; Chapman1985; Justice 1987:91–96, Anderson,1991) The earliest bifurcate forms will occasionally exhibit corner notching whereas later corner notched
varieties exhibiting serration. (Ellis 1991). Moreover, later bifurcate points sometimes have stemmed bases that provide a continuous sequence into the Middle Archaic (Chapman and Keel 1979:53-54 Ellis 1991:57). These findings support the notion that morphological changes in point types occurred gradually through time (Ellis 1991:57). Data from subsurface archaeological excavations and surveys show that Early Archaic peoples likely relied to a greater extent on localized sources of tool-stone than during earlier periods (Anderson and Sassaman 2012:72). In general, there is an increase in the abundance of Early Archaic sites in the southeast, and these findings support the conclusion that populations sizes were increasing as group territories were contracting (Anderson 1990:198–201, 1996b:160–163; Dunbar and Webb 1996:352; Walthall 1998). Settlement subsistence models suggest that Early Archaic groups in the southeast organized themselves within mobile bands that were geared toward the exploitation of specific physiographic environments such as drainage basins (Anderson and Hanson 1988 or raw material sources (Daniel 2001). Anderson and Hanson’s (1988) “band-macroband” model of Early Archaic settlement in the Savannah River Valley also supports the idea that bands were loosely affiliated with larger networks or “macrobands” that would aggregate on seasonal cycles for information exchange (Anderson and Sassaman 2012:72; Anderson 1996a:39–45; Anderson and Hanson 1988). At the local level, band sized groups in the Savannah River Valley incorporated mobility strategies that emphasized seasonal movement within the river basins based on the placement and availability of subsistence and raw material resources (Anderson and Hanson 1988). According to Sassaman, Hanson, and Charles (1989), estimates place annual foraging rounds in the Savannah River Valley at no greater than 350 linear kilometers. Anderson and Hanson (1988) suggest further that Early Archaic subsistence rounds in the Savannah River Valley included a mixed mode of collecting during the winter and change to an alternative
foraging system for the remainder of the year. Early Archaic subsistence practices were primarily marked by an increase in generalist foraging strategies, although a reduction in foraging range in response to postglacial climate change.

**Middle Archaic (8900–5800 cal yr BP)**

The Middle Archaic, dating from 8,900 cal yr BP-5,800 cal yr BP corresponds with the onset of the Hypsithermal, a climate interval consisting of increased temperatures and lower precipitation across the globe. This period is association with a shift from mesic oak forests retreating to the north as pine stands invaded the Coastal Plain uplands (Anderson and Sassaman 2012:73; Delcourt and Delcourt 1985; Watts et al. 1996). The increase in temperature and aridity during the period may have increased the favorability of riverine areas over those situated in the uplands (Anderson and Sassaman 2012:73; Brown 1985:219–221). A number of dramatic cultural adaptations have been dated to the Middle Archaic. In the Southeast, the period is marked by increasing social and technological complexity evidenced by the first occurrences of monumentality and long distance social interaction (Sassaman and Anderson 2004; 2012; Smith 1986). Most notably the period is identified by the introduction of stemmed projectile points, bifaces, and an increase in the abundance of ground stone artifacts recovered from lithic assemblages. These findings imply an increased reliance on seeds and nuts. Anderson and Sassaman (2012:74) recognize five additional cultural characteristics of the Middle Archaic including increased use of freshwater shellfish, construction of earthen mounds, establishment of long distance trade networks, lithic innovations such as the use of bannerstones, and evidence of violence and warfare. Most importantly, these changes reflect increased social complexity and the beginnings of a regional trend toward sedentism.
The Middle Archaic is recognized by a sequence of diagnostic projectile points initially defined by Joffre Coe from excavations at stratified sites in North Carolina. (Sassaman and Anderson 2012; Coe 1964). In the Savannah River Valley the Middle Archaic is recognized archaeologically by a transition in projectile point morphology to points that have stemmed bases. Kirk Stemmed (8000-7800 \(^{14}\)C yr BP), square-stemmed Stanly 7800-7500 \(^{14}\)C yr BP), Morrow Mountain (7500-6000 \(^{14}\)C yr BP), and Guilford 6000-5000 \(^{14}\)C yr BP) are point varieties that have been identified in the immediate area (Blanton and Sassaman 1989; Chapman 1985; Coe 1964). At Topper and at other quarry sites throughout the Savannah River Valley Middle Archaic and Late Archaic assemblages are sometimes mixed, but can be distinguished based on extent of weathering in the form of cortication found on the exterior surfaces of the points. The relationship between cortication and the age an artifact has been in the ground was first noted by A.R. Kelly (1938). Kelly observed that the degree of “decomposition” a given piece of chert had undergone was directly related to the antiquity of the specimen in question (Kelly 1938:4-8). Accordingly, chert specimens of less than 1,000 years of age typically do not exhibit evidence of weathering in the form of exterior cortication. There is some evidence for variation in the distribution of Middle Archaic points by landform. For example Blanton and Sassaman (1989:58) have found higher numbers of Guilford points in the Piedmont, North of the Santee River, with much fewer specimens identified from the Middle Savannah River Valley. Likewise the distribution of lanceolate point types subsumed under the acronym “MALA” also varies by physiography. MALA refers to a Middle to Late Archaic stemmed and notched lanceolate point originally discovered at the Pen Point Site in Barnwell County, South Carolina (Sassaman 1985:1-17). The distribution of MALA points is centered on the Middle Savannah River Valley in and near Allendale County, and is rare from the Piedmont River valleys to the north. MALA
points have since been renamed and are commonly referred to today as Allendale points. These discoveries have been used to support the proposition that “separate but contemporaneous peoples occupied South Carolina” during the Middle Archaic; one population centered on the Coastal Plain and another occupying the Piedmont (Sassaman and Anderson 1995:29).

**Late Archaic (5,800-3,200 cal yr BP)**

The Late Archaic (ca. 5800-3200 cal B.P.) is distinguished from the Middle Archaic period based on a transition from warm, dry climate characteristic of the Hypsithermal to near modern conditions by 5,800 cal yr BP. Amelioration in climate likely led to widespread abundance of favorable resources across the Southeast which may have led to increased population growth throughout the region (Anderson and Sassaman 2012:74). Culturally, the Late Archaic in Eastern North America is characterized by increased organizational and technological complexity. Developments that distinguish the Late Archaic from the Early Archaic include the introduction of plant domestication, and increases in long distance trade of prestige goods, construction of monumental architecture, complex burial practices, warfare and sedentism when compared with earlier periods. (Anderson and Sassaman 2012; Claassen 1996; Griffin 1967; Kidder 2006, 2010; Russo 2010; Sassaman 2010a). Technological adaptations of the Late Archaic Southeast include innovations in stone tool production and the widespread adoption of pottery in the Savannah River Valley. Projectile point technologies during the Late Archaic placed an emphasis on the production of hafted bifaces with characteristic “broad blades and large robust stems” (Anderson and Sassaman 2012:75). The Savannah River Stemmed point (Coe 1964:pp 35) is one such example, and is found in relatively high abundances in the Savannah River Valley and western Allendale County, S.C. Technological innovations such as the production of soapstone vessels (thought to post date 4200 cal yr B.P.) played a significant
role in cultural systems of the Late Archaic as these items were important exchange items that facilitated the movement of resource goods throughout the region (Anderson and Sassaman 2012:75-76). Such innovations combined with favorable climate enabled a number of trends in mobility and settlement during the Late Archaic including increased sedentism, (with the possible exception of upland areas where groups may have relied to a greater extent on higher seasonal rates of mobility), the incorporation of more permanent settlements, and intensified patterns of land use (Anderson and Sassaman 2012).

The cultural developments of the Late Archaic suggest an increased reliance on riverine resources as evidence for shellfish exploitation is seen at a number of sites throughout the region. The construction of shell mounds ‘along the rivers of’ the Coastal Plain is has been described as early evidence of monumental architecture and perhaps increased sedentism (Russo 1996, 2004, 2010). While some technological innovations occur earlier in regions outside the Southeast, the development of pottery occurred earlier in the South Atlantic area and represents “some of the earliest” pottery in North America (Sassaman and Anderson 1995:29). These discoveries have prompted researchers to divide the Late Archaic further into two sub periods; the preceramic and ceramic periods (Sassaman 1993, 2010b, 2010b). The pre-ceramic (5000-4500\(^{14}\text{C yr BP}\)) is primarily identified based on the presence of Savannah River Stemmed bifaces combined with a lack of pottery (Coe 1964). The subsequent ceramic Late Archaic was initially distinguished based on three ceramic phases; the Stallings I phase (4,500-4,000\(^{14}\text{C yr BP}\)), the Stallings II phase (4,000-3,400\(^{14}\text{C yr BP}\)), and the Stallings III phase (3,400-3,000\(^{14}\text{C yr BP}\)) (Sassaman and Anderson 1990:184-185; Stoltman 1974 More recent research has classified the Late Archaic ceramic as belonging to the Early (4,600-4,450 cal BP) and Classic (4,200-3,800 cal BP) Stallings phases based primarily on variations in mobility and settlement subsistence decisions.
Accordingly, the early period is dominated by greater seasonal mobility and a lack of permanent settlements, whereas later periods are characterized by the establishment of circular villages with permanent structures (Sassaman 2010:176).

**Woodland Period (3200–1000 cal B.P.)**

**Early Woodland Period (3,200–100 B.C.)**

The Woodland period begins approximately 3,200 cal yr BP and was traditionally distinguished from the preceding Archaic period by the widespread adoption of pottery, sedentism, and food production (Anderson and Sassaman 2012:70). However, by its end, the Woodland period witnessed the “emergence of compact, hierarchically organized societies” (Anderson and Sassaman 2012:114). Today, the onset of the Woodland period is more ambiguous, and has been described by Anderson and Sassaman as a period of diminished archaeological resolution as many of the characteristics that were previously used to define the period are now known to have had their origins in the Archaic (Anderson and Sassaman 2012:115). Culturally, the Early Woodland has come to be recognized as a period of large scale abandonment whereby groups practiced increased mobility and dispersed from centralized locations. Archaeological evidence supports a reduction in long distance exchange perhaps related to a significant population collapse (Anderson 2010; Kidder 2010:24; Sassaman 2010b:231). Apart from the breakdown of extensive trade networks many shell middens that served as social interaction centers were also abandoned during the initial Woodland period (Sassaman et al. 1990:13; Sassaman 2010b:230-231) More importantly, the period has been identified with a time of cultural differentiation and regionalism as people in different “sub regions of the Southeast adopted alternative land use practices at this time” (Anderson and Sassaman 2012:115). Increases in the remains of terrestrial fauna at Early Woodland sites in the
Southeast combined with changes in lithic technology imply a transition away from delayed return systems and more in line with those focused on immediate subsistence returns. Moreover, the irregular use of sites is another indication of increased mobility during the Early Woodland in the Southeast U.S. Many of these changes are hypothesized to have been brought about by fluctuations in climate, the collapse of social networks, or some combination of both (Anderson and Sassaman 2012:115; Anderson 2001; Fiedel 2001; Gunn 1997; Kidder 2006, 2010; Marquardt 2010; Russo 1996; Sassaman 2010a; Thomas 2010; Thompson 2010). Kidder proposes that large scale climate fluctuations facilitated a cooling trend during the Early Woodland that may have brought about wetter conditions and subsequently increases in the potential for flooding events (Kidder 2006:215). Such conditions may have facilitated the abandonment of some local areas but likely not entire sub regions (Anderson and Sassaman 2012).

Jefferies (2004) recognizes four primary trends that characterize the Early Woodland period. These trends include: 1; widespread adoption of pottery, 2; increased dietary importance of seeds, 3; increased sedentism, and 4; more elaborate mortuary and burial practices. Although pottery is first observed in the archaeological record during the Later Archaic, distinct variations in the morphology and surface treatment of pottery vessels became more pronounced during the Early Woodland (Anderson and Sassaman 2012). Such variations served the basis for distinguishing between different cultural traditions of the region. Caldwell (1958) and later Bense (1994:114–19) recognized Woodland traditions across multiple regions including the Gulf Coastal Plain, interior Mid-south, Southern Appalachians, and the Middle Atlantic coastal Plain. During the Woodland Period mound construction became intensified with structures serving as primary interments for the dead. Mound construction was present throughout the Lower
Mississippi Valley and also associated with the Adena culture of the Ohio River Valley to the north where mounds formed as the result of “accretional deposits resulting from repeated mortuary events” (Anderson and Sassaman 2012:117, Clay 1998). Although horticultural practices were developed as early as the Late Archaic, the practice of gardening became of greater emphasis to prehistoric groups of the southeast during the Early Woodland (Smith 1987, 1992, 2006). Moreover, increased use of nut mast such as hickory and acorn exploitation indicate additional use of plant resources during the Early Woodland (Anderson and Sassaman 2012:121). In the Savannah River Valley the Early Woodland is distinguished from the Late Archaic period based on the combined appearance of small notched and stemmed bifaces in addition to Refuge pottery (Sassaman et al. 1990, DePratter 1976). Refuge pottery, as a complex, was first defined by Waring (1968) based on materials recovered from the Refuge site on the South Carolina coast. Four types of surface treatments were identified within the Refuge ceramic sequence and include: Refuge Punctate, Refuge Incised, Refuge Simple Stamped, and Refuge Dentate Stamped. These surface decorations form the basis of the ceramic chronology of the Savannah River Valley with the earlier phase “Refuge I” (3000-2800 14C yr BP) consisting of the Punctate and Dentate Stamped varieties, and “Refuge II” (2800-2600 14C yr BP) comprising the plain and simple stamped types (Sassaman and Anderson 1990:190-192). Refuge pottery has been identified from the upper 20cm of sediment at the Topper Site and likely indicates an Early Woodland presence at the site.

**Middle Woodland Period (100 B.C.–A.D. 500)**

The Middle Woodland period is characterized as a time of increasing social and technological complexity throughout the southeastern U.S. The period is marked by an increase in elaborate surface treatment of ceramic vessels, and an increased role of horticulture in
subsistence. Cantley and Joseph (1991) describe a number of cultigens that appear during the Middle Woodland period in the southeast including marsh elder and maygrass. Maize and squash may have been added to the diet during this period as well (Cantley and Joseph 1991), although Gremillion (2002) has found little evidence for the dependence on maize at this time. According to Anderson and Sassaman (2012:126) although undomesticated plants were supplemented with products from the Eastern Agricultural Complex, widespread agriculture was not a predominant practice throughout the Southeast until after AD 900. Anderson and Sassaman (2012) suggest that the “defining feature of the Middle Woodland is the spread of mortuary mound ceremonialism rooted in the Hopewell tradition of the Ohio River Valley” (Anderson and Sassaman 2012:122; Bense 1994:162; Chapman and Keel 1979; Smith 1986). Known as the Hopewell Interaction Sphere, a number of manifestations of the Hopewell tradition spread south, including the occurrence of conical and occasional platform mounds and the long distance exchange of goods. The largest of these manifestations was the Pinson mound complex in western Tennessee (Anderson and Sassaman 2012:122).

In the Savannah River Valley, technological changes in ceramics and lithic assemblages continue to be the primary method that archaeologists use for distinguishing among different local Middle Woodland traditions (Anderson and Sassaman 2012). The Middle Woodland in the Savannah River Valley is marked by the appearance of Deptford ceramics and the addition of small triangular projectile points (Sassaman and Anderson 1990). Deptford ceramics may be divided into two sub-phases; Deptford I (2600-2000 14 C yr BP) consisting of plain, check stamped, and simple stamped forms, and Deptford II (2000-1500 14 C yr BP) which includes surface treatments that are cord marked, complicated stamped, and punctate (Sassaman and Anderson 1990:192-193). Middle Woodland lithic assemblages from the Savannah River Valley
lack evidence of the stemmed bifaces characteristic of the Early Woodland period. In their place, diagnostic triangular points such as Badin and Yadkin types become more common and widespread throughout the region.

**Late Woodland Period (A.D. 500–1000)**

The Late Woodland period was once characterized as an enigmatic transitional time where specific aspects of social organization (e.g. long distance exchange networks) that were prominent throughout the Early and Middle Woodland begin to break down. Archaeologically, the Late Woodland period marks a decline in the importance of the Hopewellian mound centers of the Midwest, and along with demographic shifts in population, leads to more localized spheres of interaction by A.D. 500. According to Anderson and Sassaman (2012:126) the Late Woodland was characterized by an emphasis on interregional connections and population shifts that may have partly resulted from climate change during the Late Holocene. The emergence of ceremonial mound complexes along the Gulf coast, and Lower Mississippi River Valley is testament to such an apparent demographic shift in population during this time. While settlement patterns across the region varied to some extent according to environmental setting or socioeconomic organization, in general there was a temporal transition from an emphasis on the exploitation of small tributaries and their associated upland environments, to one of more permanent settlements on the floodplains associated with large rivers and associated basins. In the vicinity of the Topper Site in the Savannah River Valley the Late Woodland is separated into two sub-periods (Early and Late) based on differences in ceramic typology (Sassaman and Anderson 1990:202-206). The early period (1500-1200 14C yr BP) is associated with the introduction of sand-tempered plain, cord-marked, and fabric-impressed pottery and the absence of Deptford wares (Sassaman and Anderson 1990:202). Pottery diagnostic to the later sub period
Diagnostic lithics of the Late Woodland period are primarily triangular hafted bifaces often called Hamilton points. These types were manufactured until historic times and are only diagnostic when recovered in context.

**Mississippian Period (1000 A.D.-1600 A.D.)**

The Mississippian period in the Southeast U.S. represents a time of increased social complexity consisting of chiefdom level societies that extends from ca. A.D. 1000 to European contact in the sixteenth century (Anderson and Sassaman 2012:151). Traditionally, the Mississippian period was defined based upon distinct material culture and architecture including localized evidence of shell tempered pottery in addition to the construction of platform mounds. In recent decades Mississippian, as a culture complex, has come to be defined more so as a temporal period rather than strictly based on specific aspects of material culture. According to Anderson and Sassaman (2012) and others, Mississippian sites typically have evidence of one or more of the following characteristics: wall trench houses; flat-topped pyramidal mounds; a subsistence adaptation heavily reliant on maize agriculture; and a social organization consisting of hereditary inequality (Alt and Pauketat 2011; Anderson 1994; Dye 2012; Griffin 1967; Knight 1986; Pauketat 2007; Smith 1986; Steponaitis 1986:387–388). The Mississippian period is most notably identified with the large mound complex and associated chiefdom at Cahokia in the Mississippi River Valley and the associated settlements that were dispersed across the American Bottom. Chiefdom societies incorporate a hierarchical settlement pattern including platform mounds at the center with smaller villages and hamlets dispersed peripheral to the mound complexes. Mississippian societies were present in the Savannah River Valley by 1000-1100 cal BP. While no mound sites have been identified in the immediate vicinity of the Topper Site, the possibility exists that they could have been present in the area at some point during the past but
have been destroyed by erosion or modern activities, or were too low and small to be observed

The Lawton Mound, a Mississippian Platform mound center on the banks of a slough of the Savannah River in Allendale county South Carolina is the closest identified mound to Topper. The site includes two platform mounds approximately 3m in height and Due to its small size only on approximately three acres of property, the site has been described as having contained “at best at a small resident population” (Stephenson 2010:12). Because the distribution of possible settlements associated with the Lawton Site is presently unknown, the potential recovery of Mississippian material culture from Topper could provide more information about how Mississippian people in the region distributed themselves on the landscape. King (2000) suggests that Mississippian mound sites have been recorded to the north of the Savannah River Site, and apart from Lawton “another two are known to the south of the facility that were abandoned by ca. 1450” (King 2000:12). Anderson (et al. 1995:273) identify no fewer than two Mississippian platform mound centers north of Topper in the Savannah River Valley (Tate, and Beaverdam Creek) and note the uncertain construction of at least three additional mound centers (Hollywood, Mason’s Plantation and Rembert).

Based on research in the region, three Mississippian sub periods have been defined based on ceramic typology. The Early (A.D. 900-1200), Middle (A.D. 1200-1350), and Late (A.D. 1350-1540) Mississippian. Ceramic types diagnostic to the Early Mississippian or Lawton phase, include Savannah series Complicated Stamped, Burnished Plain, Fine Cord Marked, and Check Stamped types. The Middle Mississippian or Hollywood phase consists of Savannah Check Stamped, Mississippian Plain, Burnished Plain, Savannah Complicated Stamped, Irene Complicated Stamped, and Sleepy Hollow Complicated Stamped (Anderson 1994:370; DePratter 1979; King 2000, 2003; Sassaman et al. 1990). Late Mississippian sites are rare or are largely
absent in the middle Savannah River Valley and may reflect a period of abandonment of the region (Anderson 1994). Evidence suggests that the region was not occupied at the time Hernando DeSoto entered the area in 1540 A.D. Lithic technology in the Savannah River Valley during the Mississippian period is represented by small, triangular projectile points. Moreover, research suggests that the projectile points from this period may be differentiated from their Woodland predecessors by specific variations in basal morphology through time (Anderson et al. 1982; Blanton et al. 1986:107-110; Sassaman and Anderson 1990:167). For the purpose of this study, the culture history of the region provided herein can serve as a template to compare with the results of archaeological investigations at Topper.

Figure A1-2
Culture Chronology for the Middle Savannah River Valley. Adapted from Anderson 1994:159 and Sassaman et al.1990. While no diagnostic points are present in the Savannah River Valley that predate 12,500 cal B.P, two types do occur in the Mid Atlantic.
Figure A1-3
Projectile point chronology for Middle Savannah River Valley. (Artifact images courtesy of Albert C. Goodyear). (Sassaman et al. 1990).
Figure A1-4a
Extent of sea level rise off the Southeast U.S. Coast for last 18,000 years with transects for measures of the slope of the continental shelf by latitude.

Figure A1-4b
Extent of sea level rise for select time periods off the Virginia and North Carolina coast using data from Balsillie and Donoghue (2004). The Virginia and Delmarva Coast exhibit broad coastal zones with gentle slopes. High densities of Clovis points have been recovered from river drainages that empty in proximity to such areas. The North Carolina coast exhibits a narrow Coastal Zone. (Image adapted from Lowery et al. 2012 using data from Basillie and Donoghue 2004).
Figure A1-5

Map of the Southeast coast showing extend of sea level rise for select time periods. Area highlighted reflects broad coastal zones.
Enlarged map showing extent of sea level rise off the coast of South Carolina for select time periods. Shoreline at MWP1A illustrated in red. Clovis shoreline illustrated in black. Shoreline at MWP1B illustrated in yellow. Sea level rise had a much greater affect on the total area of the continental shelf submerged during MWP1B and the Younger Dryas (Yellow) than it did during previous intervals, (Clovis; Black, and MWP1A; Red). The area submerged at each interval is a direct result of the gradient of the continental shelf. A greater extent of the continental shelf edge was breached during MWP1A in locations where the shelf is less steep and in regions where broad coastal zones intersect major rivers.
County level Distribution of Clovis points for the Southeast U.S with paleo shoreline at specific intervals. Darker shades indicate increased point densities. Data obtained from PIDBA. Map courtesy of Thaddeus Bissett. Sea level estimates reconstructed from Basillie and Donoghue 2004.
Figure A1-8
Distribution of Post Clovis points for the Southeast U.S with paleo shoreline at specific intervals. Darker shades indicate increased point densities. Broad coastal zones are those where contours are widest. Data obtained from PIDBA. High densities of points occur where major rivers intersect and empty onto broad coastal zones. Data not available for New Jersey. Map courtesy of Thaddeus Bissett. Sea level estimates reconstructed from Basillie and Donoghue 2004.
Figure A1–9
Mean difference in slope for the continental shelf at the -55m isobath by point density per River drainage. Drainages with greater than 20 fluted points empty into broad coastal zones.

Figure A1–10
Mean difference in slope (m) for the continental shelf at the -71m isobath by point density/River drainage. The slope of the continental shelf was measured along 36 transects from the modern shoreline to the -71 isobath to examine how shorelines were changing during the Late Pleistocene and to evaluate patterns in the distribution of projectile points by slope. Results show that drainages with more than 20 fluted points empty into broad coastal zones.
Table A1–1.
The slope of the Atlantic Coast from the -55, isobath by latitude for 36 transects from South to North. Clovis points by river drainage. Higher densities of points correspond with low gradient slopes.

APPENDIX 2

CHERT VARIETIES AND CONDITIONS FOUND AT TOPPER AND THE RESULTS OF AN UNDERWATER CHERT BOULDER SURVEY
In 2010 a survey was carried out to document potential sources of chert from the base of a chute channel of the Savannah River adjacent to the Topper Site. Individual chert specimens were recovered, weighed, measured, and examined for visual and material characteristics. The following table and images present the results of this survey. All chert specimens were recovered by the Underwater Archaeology Division of the South Carolina Institute of Archaeology and Anthropology and Jesse Halligan of Texas A&M University. Images provided by Jesse Tune. An objective of the survey was to evaluate whether or not chert cobbles from the river bed were suitable for tool manufacture. The results demonstrate that some chert cobbles from the study retain interiors that are of high quality and thus could have suitable for chipped stone tool production. Cobbles were predominantly nodular in form with an average weight of 11.82kg. Cobble lengths ranged in size from 11.7cm to 42cm. Cobble widths ranged from 13cm to 41cm, and thicknesses ranged from 9.5 to 25cm.
Allendale chert cobbles from Topper Site and adjacent River. A; Nodular Broken cobbles, B; Terrestrial cobble with flaws, C; Terrestrial cobble, D; River chert cobble, E; Broken river chert cobble, F; Tabular river chert. The terrestrial chert is lighter in color and has a chalky white exterior cortex compared with the dark smooth exterior surface of the river cobbles.
Figure A2-2
Map of the Topper Site relative a chute channel of the Savannah River. Chert boulders are present within the river base of the channel and were likely exploited by Clovis and subsequent Holocene prehistoric occupants at the site.

APPENDIX 4

RESULTS OF SEDIMENT PARTICLE SIZE ANALYSIS FROM THE HOLOCENE AND PLEISTOCENE TERRACE AT THE TOPPER SITE (38AL23)
In 2010 Harris and colleagues conducted a high resolution particle size and microscopic analysis of 140 sediment samples recovered from the Holocene and Pleistocene Terrace at the Topper Site. The goal of this study was to provide a better understanding of the sedimentological context of the Quaternary deposits at the site and in addition to sediment transport and site formation processes (Harris et al. 2010:1). The sediment samples were analyzed to evaluate sediment texture and grain composition. According to Harris et al, (2010) samples were processed in the lab using a CILAS1180L laser particle size analyzer and were subsequently analyzed for statistical parameters. Results are presented in Figures A4-2, A4-3. The results of the analysis show that the deeper deposits, at the base of the profile (95.4m) exhibit sediments that are slightly courser than higher in the profile, have a higher kurtosis, and lower standard deviation (Harris et al. 2010:1). Kurtosis, (peakedness) of a grain-size distribution compares sorting in the central portion of the population with that in the tails. Skewness is the degree of symmetry or asymmetry of the grain-size distribution, which is a function of the mean, median, mode, and kurtosis. As the mean sediment grain size becomes finer, there is a corollary increase in the standard deviation (Figure A4-4). This pattern corresponds with a “fining upwards” sequence through the Pleistocene terrace. According to Harris et al. (2010), the accumulation of more medium sands throughout the lower unit indicates that the influence of the river was at a greater distance during deposition of the Terrace than it was during later periods. These attributes are also indication of increased accumulation of mud via pedogenic processes (Harris et al. 2010:1). There is a discontinuity between the lower floodplain alluvium and overlying colluvial deposits that begins at 97.20M and extends to 98.00M, the base of the Clovis deposits. Erratic spikes indicate repetitively finer and coarser deposits throughout this unit (97.20-98.0m), and were identified in the field as “graded beds”
Harris et al. 2010:1. This area is interpreted as a series of high energy deposits and is consistent with the movement of a braided river system in closer vicinity with the site (Harris et al. 2010).

Close up of Stratigraphic profile at the Topper Site showing Holocene and Pleistocene Sands deposition. Middle Archaic assemblage visible at 98.44M. Pleistocene gravel lens visible between 97.65m and 97.48m associated with Upper Pleistocene Sands. Contact of Pleistocene Terrace at 97.13m. Profile is East wall of N247 E136.
APPENDIX 5

TOPPER GEOCHRONOLOGY AND DATING
Appendix 5 presents results of the geochronological investigations conducted at the Topper Site. Tables A5–1 to A5–3 present the radiocarbon and Optically Stimulated Luminescence (OSL) dates calculated from analyses conducted by Waters et al (2009) and run on the Topper Site sediments. Table A5–4 offers the provenience locations for the 2011 Sediment samples selected for OSL dating. Figures A5-1 and A5-2 are photos of the geoscience team conducting geoarchaeological investigations at the Topper Site. Figure A5-3 is a map showing the provenience of sediment samples selected in 2011 from the Pleistocene Sands and Terrace for OSL dating. The sediment samples extracted from these locations are presented in Figures A5–4 to A5–6. Finally, Figures A5–7 and A5–8 present the sediment sample locations for the Holocene and Pleistocene Sands 2011 4m x4m block excavation on the Alluvial Terrace at the Topper Site (38AL23).
AMS radiocarbon measurements from the Topper Site (Adapted from Waters et al. 2009).

APPENDIX 6

HISTORY OF POLLEN RESEARCH IN THE SOUTHEAST U.S.
Appendix 6 presents a history of pollen research in the Southeast U.S. This section includes the results of paleoenvironmental reconstructions for selected sites throughout the region based on the acquisition and examination of sediment cores. Maps detailing these reconstructions are presented in Figures A6-1-3.

As early as the 1890’s, researchers such as C.W. Weber noticed the potential of fossil pollen analysis as a means of examining the succession of vegetation through time (Erdtman 1924). However, the analysis of pollen sequences stems from the research of a Swedish geologist, Lenart Von Post, who in the early twentieth century developed a method for quantifying pollen assemblages from stratigraphic contexts. Von Post (1946) presented the geographical array of pollen spectra as percentages of the sum of the pollen grains counted for a given slide, with pollen spectra plotted against their stratigraphic position through the sediment profile. Such depictions allowed researchers to make spatio-temporal comparisons regarding the distribution(s) of pollen from individual taxa, and revolutionized research geared toward paleovegetation reconstructions.

Pollen research in the Southeast U.S. dates to the late 1920’s. In one of the earliest studies, Lewis and Cocke examined the pollen sequence of sediments recovered from the Dismal Swamp peat bog of Virginia (Lewis and Cocke 1929). They were able to identify the depths at which specific arboreal taxa such as pine, oak, and hickory made their greatest state of development with little open grasslands occurring during this period (Lewis and Cocke 1929). However, at the time it was not possible to provide more precise age brackets for pollen sequences because researchers could only order the distribution of specific taxa in relation to each other by percent. With the development of radiometric dating techniques during the mid-twentieth century, (Arnold and Libby 1949), alongside cross-dating techniques taken from
dendrochronology, it was possible to date pollen sequences with some degree of accuracy. Researchers were able to demonstrate the effects of late glacial climate change on vegetation across different regions.

During the 1970’s, researchers devoted to pollen analysis in the Southeast (Delcourt and Delcourt 1977, 1979; Watts 1970; Watts and Struiver 1980) sought to develop models that could explain specific climactic forcing mechanisms responsible for changes in the structure and distribution of paleovegetation. Among the notable discoveries was the variation found in the distribution of plant taxa as climate became more unstable during transitions between glacial and interglacial periods (Delcourt and Delcourt 1977; Watts and Struiver 1980). A general trend became evident, with plant species such as spruce, conifers, and birch dominant during full glacial (stadial) period and more temperate forests situated to the south as a result of cold climate (e.g. Delcourt and Delcourt 1984, 1993; Watts and Struiver 1980). As climate became variable, yet warmer during the late glacial interval (13,000—10,000 cal yr BP), hardwoods such as oak, hickory, and herbaceous species increased in abundance, initially dispersing from southern latitudes, and then trending in a northerly direction as climate became less harsh.

In a seminal study geared toward reconstructing Late Pleistocene paleoenvironments, Delcourt and Delcourt (1982) hypothesized that shifts in dominant air mass boundaries were responsible for variation(s) in continental pollen sequences, and that these sequences could be used to map changes in vegetation by latitude through time (Figure A6-1). Delcourt and Delcourt (1984) developed vegetation maps for Eastern North America for select intervals of time throughout the Late Pleistocene. These maps were based on pollen studies conducted throughout the Eastern Woodlands of North America. Accordingly, the maps in Figure A6-1 present the potential distribution of vegetation types throughout the region for intervals at 28,000 cal yr BP,
18,000 cal yr BP, and 13,000 cal yr BP, and 8,000 cal yr B.P. Based on this research, major vegetation types since Late Glacial Maximum were classified according to three latitudinal boundaries (Delcourt and Delcourt 1984). The first boundary is north of the 39th parallel. During cool periods such as the Full Glacial and Younger Dryas, Northern latitudes were dominated by boreal, coniferous taxa such as spruce (Picea) and fir (Abies). With the onset of more moderate temperatures during the early Holocene, birch (Betula), elm (Ulmus), oak, maple, hickory (Carya) and other deciduous forests increased in distribution.

Between latitudes 33º and 39º N, boreal forests including Jack Pine and spruce were the dominant species whereas oak represented only a minor component throughout this region. Due to the dry, arid climate characteristic of the Full Glacial, forests in these latitudes are likely to have been dispersed over the landscape, only occupying regions where moisture was abundant enough for tree survival and growth. Closed canopy forests were rare.

The boreal forests of the full glacial were replaced by mixed deciduous forests during the LGIT (Delcourt and Delcourt 1985; Delcourt and Delcourt 1987). Across this interval, vegetation was unstable, as increases in mean annual temperature, summer insolation, and the length of the growing season aided the expansion of hardwoods dominated by oak, hickory, and birch, but also consisting of walnut (Juglans), elm (Ulmus), willow (Salix nigra), American beech (Fagus grandifolia), and sugar maple (Acer saccharum) (Delcourt and Delcourt 1982). This mixed conifer-deciduous regime was widespread throughout Eastern North America, and began to retreat north after 12,500 cal yr BP. By 9,000 cal yr BP. Warm temperate species, including sweet gum (Liquidambar styraciflua), chestnut (Castanea dentate), and red maple, replaced the coniferous forests by 9000 cal yr BP (Delcourt and Delcourt 1982).
During the Late Pleistocene, vegetation south of 33º maintained a state of dynamic equilibrium, with little change in stability through time. Oak and hickory were dominant during the full glacial interval, as warmer, temperate conditions allowed for the expansion of deciduous forests throughout much of the southeast (Delcourt and Delcourt 1985). However, the arid climate and variable soils in some areas led to the formation of vegetation communities consisting of park like savannahs and scrublands; environments that would have been suitable for large numbers of grazing mammals to thrive in (Graham and Mead 1987). By the Hypsithermal, the homogeneous hardwood canopies were finally replaced when warmer and wetter climate led to an increase in species of southern pine (Delcourt et al. 1983; Delcourt and Delcourt 1985). More recent studies by Williams (et al. 2004) have found that individual plant taxa experienced unique “shifts” in the range and abundance throughout the Late Pleistocene. Most plants were found to retreat northward although others experienced east-west shifts in distribution (i.e. Picea and Pinus). Rate of change maps produced by Williams et al (2004:312-317) illustrate these shifts and are presented in Figure A6-2.

The latitudinal model developed by Delcourt and Delcourt contributed greatly to North American paleoenvironmental research. The model suggested a significant correlation between the distribution of individual plant species and the geographic position(s) of major climate gradients (Delcourt and Delcourt 1982). However, while the model worked well for predicting climate and paleovegetational changes at the regional level, it proved problematic for distinguishing similar changes at local scales. Based on evidence from palynological studies in the southeast U.S., the paleoenvironmental record is substantially variable at the local level (Watts 1980; Delcourt and Delcourt 1977, 1983). As such, more recent paleoenvironmental
research has been conducted with a goal to provide in depth site reconstructions that will provide a better understanding of the variable nature of paleoenvironmental change in the Southeast U.S.

**Paleoenvironmental Research in the Southeast U.S.**

Numerous studies have provided detailed paleoenvironmental reconstructions of the Southeast U.S. (Delcourt and Delcourt 1977, 1983, 1988, 1991; LaMoreaux et al. 2009; Jackson and Whitehead 1993; Watts 1970, Watts 1980, Watts et al. 1992, Watts and Hansen 1994; Whitehead 1981; Williams 2003; Grimm et al. 2006; Shuman et al. 2002. Many studies examine the fossil pollen record of the region and results of these analyses typically indicate shifting patterns in the structure of vegetation, in some cases abruptly over the course of the last 20,000 years owing to oscillations in climate. Moreover, paleoclimatologists have found evidence for fluctuations in climate that significantly predate 20,000 years, going back to at least 2.6 million years. These fluctuations in climate are often classified as stages based on oxygen isotope calculations obtained from sediment cores, and are referred to as Marine Isotope Stages (MIS) that document alternating warm and cold periods on our planet. The most recent Marine Isotope Stage is MIS 1 which began with the onset of the Holocene and reflects a warmer climate stage. MIS stage 2, which began approximately 24,000 years before the present, covers the Last Glacial Maximum and reflects a period of cooler global climate. Table A6–1 presents a list of MIS stages and associated age ranges for each.

There remains little consensus on how climate and vegetation has varied at the local level in the Southeast U.S. throughout the past 20,000 year (LaMoreaux et al. 2009). While many studies report a southern retreat of deciduous taxa during the Younger Dryas interval, followed by a subsequent expansion during the Terminal glacial/Holocene transition (e.g. Delcourt and Delcourt 1985; Delcourt and Delcourt 1987), the distribution and range of specific taxa have
been found to vary by site throughout the Late Pleistocene for the lower Southeast (Watts et al. 1992; Watts 1980; Watts 1970; Delcourt and Delcourt 1977; Delcourt and Delcourt 1983). In the section that follows, I provide a detailed description of the Late Pleistocene paleovegetation for the Southeast, noting specific vegetation patterns local to each site.

The majority of pollen sites in the lower Southeast provide vegetation sequences that extend at least to the last Glacial Maximum (LGM) 21,000 cal yr BP, and reveal a number of interesting patterns. At Lake Tulane, in South Central Florida, Watts and Hanson have identified an alternating pattern of pine and oak-scrub forest during the full glacial prior to 21,000 cal yr BP (Watts and Hanson 1993). Accordingly peaks in pine are considered to correlate with periods of increased precipitation during periods of ice advance. In contrast, during periods of ice retreat, an oak scrub and grassland is thought to have taken hold as the region became increasingly arid due to cooler surface waters caused by “melt water from retreating ice sheets” (Watts and Hanson 1993). Grimm et al. 2006 report spikes in pine prior to the LGM (Grimm et al. 2006) and again by 15,000 cal yr BP. Grass pollen decreases in abundance from 15-10,000 cal yr BP (Grimm et al. 2006). At the terminal Pleistocene/Holocene boundary pine is found to decrease in abundance whereas an increase in the distribution of oak was observed. By 10,000 cal yr BP vegetation for the localized area is primarily oak dominated whereas the mid to later Holocene was dominated by an increase in pine (Grimm et al. 2006). During the Younger Dryas interval 12,900 cal yr BP pollen data indicate prominent spikes in pine pollen, suggesting increased moisture availability and warmer temperatures during this period. Pollen records from North Florida including Camel Lake (Watts et al. 1992), Lake Tulane (Grimm et al. 2006), and Sheelar Lake (Watts and Hansen 1994), provide similar pollen distributions for this period. However, Willard (et al. 2007) documents a pollen record from Tampa Bay, Fl. That consists of oak
dominated pollen in association with specific herbs indicating “cooler, drier conditions during the Younger Dryas” (Meeks and Anderson 2012:112).

LaMoreaux et al. (2009) have provided a detailed examination of the pollen history at Sandy Run Creek Georgia in south central Georgia. Results for the LGM show a dominance of pine combined with high percentages of grass pollen indicating a mix of forested and prairie like conditions. During the Younger Dryas cool moist conditions are interpreted based on the “increased occurrence of mesic tress and an increase in riparian populations of alder” (Meeks and Anderson 2012:112). During the Terminal Pleistocene, there was a decrease in pine as oak increases and represents a greater percentage of the pollen sum (LaMoreaux et al.2009). The relative high percentage of grass pollen (15%) is indication that the region remained largely open across the LGM to Holocene transition.

Jackson and Whitehead (1993) provide a description of the paleoenvironment of northeast Georgia from the results of a pollen analysis of a sediment core taken from the Nodoroc Site, a wetland peat deposit in the Piedmont region of the state. Just prior to the LGM, the region was dominated by pine and oak, with hickory, spruce and fir present in significant amounts (Jackson and Whitehead 1993). Also present are high herb and shrub pollen assemblages, suggesting the site represented a local wetland in a forested landscape (Jackson and Whitehead 1993). The presence of fir and spruce in significant amounts at Nodoroc contradicts findings from contemporaneous Coastal Plain and Piedmont sites to the east and south where the percentage of such taxa are much lower.

At Rockyhoc Bay, North Carolina, Whitehead (1981) has provided a detailed description of the paleovegetation encompassing the period from 30,000 cal yr BP to the present. Just prior to the LGM dominant pollen types were found to include oak, alder, sedge, grass, birch, and
horn-beam. Pine generally represented less than 20 percent of the total pollen sum for this period. From 21,000 to 10,000 cal yr BP pine increases to as much as 76 percent of the pollen sum, with spruce and fir among other coniferous taxa present. Oak and hazel were found in low abundances while pollen from other temperate taxa was largely absent (Whitehead 1981). These vegetation types correspond well with modern regions of boreal forest in Canada (Whitehead 1981). During the Younger Dryas elevated percentages of hemlock, beech, and white pine suggest cooler, moist conditions. From 10,000 to 5000 cal yr BP the vegetation was dominated by oak hemlock, and shallow-water taxa, as well as many hardwood types. A decrease in boreal plants including spruce and fir occurred during the Early Holocene at Rockyhoc Bay (Whitehead 1981). In the southern Appalachian mountains and to the west, coniferous forests of the Late Pleistocene dominated by spruce and pine gave way to deciduous forests consisting of oak, birch, hemlock, beech, *Ostrya/Carpinus*, willow, and elm. As these forests transitioned from boreal to mesic in composition they were likely similar to extant northern hardwood forests of the modern Northern U.S. After the onset of the Holocene, these forests gave way to vegetation dominated by oak and chestnut forests, and finally to the modern oak-hickory forests evident throughout the region today.

At Anderson Pond, located along the Eastern highland rim of the Cumberland Plateau of Eastern Tennessee, Delcourt (1979) has provided a detailed description of the paleoenvironment of the region dating from 25,000 cal yr BP to the present. Prior to the LGM, vegetation predominantly consisted of coniferous taxa including northern pine, spruce, and fir. In addition to coniferous species, deciduous taxa such as oak, ash, hickory, birch, and walnut were also present (Delcourt 1979). From 19,000 to 18,000 cal yr BP pine remained in abundance, though a decline in spruce and fir is noted. By 18 000 cal yr BP pine increases to as much as 87 percent of
the pollen sum, while spruce and fir occur in minute amounts (Delcourt 1979). From 16,300 to 12,500 cal yr BP, pine declines in abundance while an increase in spruce and oak is noted. Ballard et al. 2012 report a transition to a more mesic deciduous forest by 16,879 cal yr BP. Beech and sugar maple increase in dominance by the latter part of this period. From 12,500 to 8000 cal yr BP, a mixed mesophytic forest was in place at Anderson pond, followed by a high influx of oak, ash, hickory and alder during the mid-Holocene (Delcourt 1979).

At Cranberry Glades, West Virginia, Watts (1979) has documented a pollen sequence that demonstrates a progression of vegetation change similar to that found at Anderson Pond. Accordingly, after the LGM forests transitioned from spruce pine and fir dominated forests to those consisting of more mesic species after 14,000 cal yr BP (Watts 1979). By 11,600 cal yr BP a change to a more xeric deciduous forest is documented based on the recovery of oak chestnut and hickory pollen (Watts 1979). The dates for the coniferous to mesic deciduous transition are widely similar throughout the Appalachians. At Browns Pond, Virginia a date of 11,700 cal yr BP. has been provided for the transition from mesic to deciduous forests (Kneller and Peteet 1993) and at Hack Pond Virginia this change has been reported at 10,700BP (Craig 1969). Likewise, at Jackson Pond Kentucky Wilkins et al. (1991) reports a spruce-fir forest in place from 24,500 to 12,900 cal yr BP. This was followed by a transition from coniferous to deciduous forests about 12,700 cal yr BP. (Boehm 2012) and a subsequent change to mesic deciduous taxa by 11,600 cal yr BP. Mesic taxa were replaced by oak-hickory-chestnut forest from approximately 8000 to 4500 cal yr BP. (Wilkins et al.1991). To the south, Watts (1970) has placed the transition from coniferous to deciduous taxa at some point prior to 14,500 cal yr BP. based on the examination of pollen sequences from Bob Black and Quicksand Ponds, Georgia.
Fossil-pollen sites in the interior and western regions of the Southeastern United States are few in number (Anderson and Meeks 2012:113). However, pollen records from recorded sites suggest there was some variation compared with other sites throughout the Southeast. A sediment core extracted from Goshen Springs, on the Gulf Coast of South Central Alabama between Louisiana and Georgia, provides a pollen history of the area that extends from the Late Pleistocene full glacial to the present (Delcourt and Delcourt 1980). Prior to the LGM (or 26,000 cal yr BP) vegetation was dominated by an oak-sweetgum-hickory forest that represents a southward shift in the vegetation boundary between southern pine and oak-hickory forests (Delcourt and Delcourt 1980). This vegetation pattern persisted throughout the full and late glacial, consisting of a broad array of deciduous and broadleaf taxa that include elm, beech, birch, ironwood, willow, and ash. During the Holocene, as climate conditions became more moderate, Goshen Springs and the surrounding region saw the development of an upland pine forests along with bottomland swamps and marshes near the coasts (Delcourt 1980). Goshen Springs and other sites from the local area differ from sites to the North and East in that vegetation patterns remained largely stable throughout the extent of the full glacial. Reports of pollen records from Cahaba Pond in Northeast Alabama indicate a rise in pine at the terminus of the Younger Dryas implying that the climate was warmer and wetter than in regions to the East (Delcourt 1983).

On the Inner Coastal Plain Watts has provided a detailed description of the paleovegetation for the past 20,000 years based on the analysis of pollen from a sediment core obtained from White Pond, South Carolina, a site located in the uplands of Central South Carolina (Watts 1980). The pollen record from White Pond contains a continuous pollen record spanning from 20,000 through 8500 cal yr BP. During the last glacial maximum (LGM) boreal
forests were the dominant vegetation type from approximately 23,500 to 14,500 cal yr BP. (Watts 1980). Pine comprised as much as 90% of the upland pollen at the site across this period. However, a significant percentage of herbaceous pollen (grasses, sagebrush, and smartweed) also appears in the pollen profile from White Pond at this time, the extent to which would not be possible to form under a closed canopy forest (Watts 1980).

By 15,000 cal yr BP, an increase in the abundance of oak and hickory suggest that deciduous taxa were beginning to invade as climate was becoming more moderate. Accordingly mesic deciduous forest vegetation dominated the pollen spectra between approximately 14,500 and 10,600 cal yr BP. (Watts 1980) demonstrating a marked decline in northern pine species across mid-latitudes of the Southeast (Delcourt et al. 1983; Delcourt and Delcourt 1985; Leigh 2006). Between 13,000 and 9500 cal yr BP, hickory, beech, and ironwood increase in abundance, while birch, elm, sugar maple, black walnut and hemlock are exclusive to this period (Watts 1980). The site transitioned to a swamp forest after 10,600 cal yr BP. (Watts 1980).

Based on the results of pollen and lithostratigraphic analysis of sediment cores spanning the past 30,000 years from sites across the Southeast U.S., a number of interesting patterns emerge (Table A6-1) Prior to the LGM, Coastal Plain sites are dominated by oak, scrub oak, and high occurrences of deciduous taxa. An exception is at Lake Tulane Florida where pine and ambrosia dominate throughout the period. Contemporaneous upland sites such as White Pond, South Carolina and Anderson Pond, Tennessee are characterized by high distributions of coniferous taxa such as spruce, fir and pine. An exception is the Nodoroc Site in Georgia where high abundances of deciduous, coniferous, and herbaceous taxa were found to occur.

During the Last Glacial maximum (LGM) and Last Glacial Interglacial transition (LGIT), most Coastal Plain sites witness a change to pine dominated forests in the north, while southern
sites such as Goshen Springs, Alabama remain in stable equilibrium, dominated by hickory, sweetgum and oak. The increase in coniferous taxa in the North may reflect cooler temperatures associated with the maximum extent of glacial ice advance. By the terminal Pleistocene nearly all sites exhibit a decrease in pine and an increase in deciduous taxa. While these results demonstrate a pattern of similarity in the distribution of vegetation across the Southeast U.S. during the Late Pleistocene, there are exceptions. For example, sites in the southern Mid-South such as Goshen Springs, Alabama consist largely of deciduous taxa throughout the duration of the full glacial while coniferous taxa dominate regions further to the south in Florida during over the course of the same period.

In addition to palynological data, research by Russell et al. (2009) have found that physical and biological evidence supports the potential existence of a “thermal enclave” located between the Southern Appalachian Mountains and the Atlantic coast during the LGM (Russell et al. 2009:1). Accordingly, the Southern Atlantic Slope would have supported a “mosaic” of forests, with an “ecological gradient” trending toward the north, with forests replacing prairies at the 35th parallel. At this boundary, the boreal forests extending from the north were replaced by prairies, and fauna consisting of “browsing proboscideans that had subsisted largely on boreal taxa were replaced by grazing proboscideans” that favored grasslands (Russell et al. 2009;1).

Incorporating recent biological, palynological, faunal and climate data, Russell et al. propose that the Southeast U.S during this period consisted of relatively warm moist climate in a region bounded by cooler drier climate to the north and west. Relatively warm waters generated by the gulf stream were “deflected” to the central Atlantic resulting in increased biodiversity than in “other unglaciated regions of North America” (Russell et al.;2009:1). Abundant pollen analyses support the notion that climate south of the maximum extent of glacial advance was
relatively moderate and consisted of relatively warm winters and cooler summers in comparison with prior conditions (Jackson et al. 2000).

The changing paleoenvironmental conditions of the Late Pleistocene, combined with associated changes in biotic resource distributions, would have greatly impacted human populations occupying regions of what is today the Southeast U.S. Increases in the distribution of deciduous plant taxa across the lower Southeast U.S during the terminal Pleistocene could have led to the exploitation of these species by humans to serve as an added dietary supplement, or for use as fuel. The buried deposits at the Topper Site present another opportunity to test for fossil pollen preservation at a stratified Clovis quarry-related site in the Southeast U.S.

APPENDIX 7

RESULTS OF POLLEN ANALYSIS AT THE TOPPER SITE (38AL23)
In 2012 a pollen analysis was conducted to determine the preservation potential for fossil pollen from the Pleistocene terrace at the Topper Site. This analysis involved the examination of a sediment core obtained via a vibra core from the base of the Pleistocene Terrace at Topper. Figures A7-1 and A7I-2 present the location from which this core was extracted along with the process of extraction. The goal of this analysis was to provide a general description of the paleoenvironment of the site and immediate vicinity during the Quaternary. The core was obtained during the March, 2012 spring field excavation with assistance from Dr. Scott Harris, professor of sediment stratigraphy at the College of Charleston, South Carolina, graduate students from the University of Tennessee, and volunteer labor. Prior to extracting the core, test samples of the Pleistocene terrace sediment matrix were obtained via auger tests (Figure A7-3). The subsequent core was extracted using a mechanical vibracore, and was divided into two sections for transport. The core measured 217cm in length, with section 1 measuring 121cm (Figure A7-4). One half of this core was taken to The University of Tennessee for pollen analysis. The second half of the core was sent to be analyzed for paleomagnetism with the goal being to serve as an alternative method for dating the terrace sediments.

The top of the sediment core begins at 4m below ground surface, well within the alluvial terrace, and from the base of the 2012 archaeological unit excavation. The provenience location from which the core was obtained is N243.05 E142.00 at a depth of 95.15m. The core extends 2.17m into sediments described as dark organic rich black gumbo clay. The top 70cm of the core consist of light brown clayey sand. From 70-80cm there is a strong brown clay. Below this strata, from 80-217cm is a dark brown clay. Figure A7-5 presents points of transition within the sediment matrix of the core. It is not known whether the entirety of the core contains sediment
associated with cultural deposits, though lithic materials having morphological attributes consistent with cultural artifacts were recovered from the base of the archaeological excavation and at the contact with the top of the core at 95.15m.

The core was brought to the Pollen research lab in the department of Geography at the University of Tennessee for analysis. In the lab, individual sediment samples were initially taken along the vertical profile of the sediment core at two arbitrary intervals. Two specimen slides were prepared and analyzed using a binocular compound microscope under a 40x objective. Each slide was systematically scanned in vertical transects. Slides were labeled numerically (H2CI 91-92, H2CI 114-115) and examined according to their depth within the core. Accordingly, slide 1 is from 91-92 cm, (94.09-94.08m) while slide 2 is from 114-115cm (93.86-93.85m).

The results of the pollen analysis are presented in Figure A7-6 and Table A7-1. From the first slide, (H2CI 91-92) a total of 377 pollen grains were identified consisting of 20 individual pollen types. In addition, charcoal, fungal spores, and indeterminate bladders were also identified. Of the pollen types identified from the sample, Oak (Quercus) was the most abundant comprising 32% of the sample. Other types identified include coniferous indeterminate bladders (29%), Pine (Pinus) (7%), Spruce (Picea) (6%), Grass (5.5%), Sweetgum (Liquidambar) (3%) Moss (3.8%), Box Elder (Acer negundo) (2%), and Ragweed (Ambrosia) (1.1%). Pollen types with less than 1% representation include Daisy (Asteracea), Wormwood (Artemesia), Nettle, American Chestnut (Castanea dentate), Birch (Ostrya), Sage, Larch (Larix), Ash (Fraxinus), Water Lilly (Nuphar lutea), Dogwood (Cornaceae), and Fir (Abies).

The second, deeper slide contains a total of 20 pollen types in addition to charcoal, fungal spores, and indeterminate bladders. Oak again was the most abundant pollen type representing
32.5% of the sample. Other pollen types identified from this slide include coniferous indeterminate bladders (24.4%), Pine (*Pinus*) (10%), Ragweed (*Ambrosia*) (5.2%), Moss (5.2%), Grass (4%), Red Ash (*Fraxinus pennsylvanica*) (3%), and *Picea* (1.7%). Other pollen types present, though with less than 1% representation include Daisy (*Asteraceae*), Wormwood (*Artemisia*), Box Elder (*Acer negundo*), Sage, Sweetgum (*Liquidambar*), Ironwood (*Carpinus caroliniana*), Aquatic Plants (*Nymphaea*), Black Gum (*Nyssa sylvatica*), Water Milfoil (*Myriophyllum alterniflorum*), Ash (*Fraxinus*), and Larch (*Larix*). Fir (*Abies*) was absent from slide two (H2CI 114-115).

A number of interesting patterns emerge from the analysis. Coniferous taxa are found in more abundance from slide H2CI 91-92. This pattern may be interpreted as a cooler, boreal climate for the period of sediment deposition contained within slide H2CI 91-92 due to the higher panacea pollen counts observed from this slide. The presence of a number of aquatic plant taxa from slide H2CI 114-115 (*Carpinus caroliniana*, *Nymphaea*, *Nyssa sylvatica*, *Myriophyllum alterniflorum*) suggest that conditions at Topper during the period these pollen were deposited is consistent with a floodplain environment, or near the border of a stream or swamp, with deep moist soil.

In sum, the results of this analysis suggest a change in vegetation at Topper during the Quaternary from temperate, moisture thriving taxa, to that of species which are boreal in nature and thrive in cooler environments. The results of the analysis could be interpreted as a pattern of general cooling from the period represented between slides H2CI 114-115 and H2CI 91-92. However, based on the low pollen counts in general, combined with the high number of undifferentiated pinaceae bladders observed from the samples, this interpretation is preliminary, and more data is needed to verify or refute these results.
Based on the radiocarbon dates obtained from Waters (et al. 2009) analysis, the sediments contained within the core are at minimum 50,000 cal yr BP. Therefore, taking these prior dates into consideration, the paleovegetational data reconstructed from the sediment core could reflect a paleoenvironmental transition from the Eemian Interglacial (120,000 cal yr BP) to 100,000 cal yr BP. However, this pattern could also reflect a climate transition that occurred approximately 60,000 -55,000 cal yr BP. More precise dating of the terrace sediments using alternative techniques is also necessary in order to establish the exact timing of the changes identified in the reconstructed pollen sequence at Topper.

APPENDIX 8

INITIAL SITE DISCOVERY AND RESULTS OF 1984 CHERT SURVEY AND AUGER TEST ON ACHROMA PROPERTY, FORMERLY THE CLARIANT AND SANDOZ PROPERTY
The presence of prehistoric quarrying activity in Western Allendale County was first documented by James B. Stoltman who conducted a survey of the Red Bluff quarries near Allendale, SC South Carolina as part of a Harvard expedition in 1964 (Goodyear and Charles 1984; Stoltman 1974. Two quarries were identified at Red Bluff, along the margin of Savannah River Swamp and were subsequently nominated to the National Register of Historic Places in 1971 by Thomas E. Hemmings due to their potential for informing about prehistoric life-ways in the region. Until the early 1980’s, the Red Bluff quarries, one of which today is known as the Rice quarry (38AL114), were the only known prehistoric quarry locales to produce high quality Flint River formation chert in South Carolina. In the 1970s and early 1980s, these quarries, along with a series of outcrops across the Savannah River in Georgia, were hypothesized to be the primary source of chert artifacts recovered in South Carolina (e.g., Goodyear and Charles 1984; Anderson et al. 1979: 10-12; Goodyear et al. 1979: 199) (Figure A8-1).

In 1973 an archaeological site was recorded by Dr. Don Sutherland on a floodplain terrace and an adjacent bluff overlooking the Savannah River on the property of the Sandoz Corporation, near Martin, SC, in Western Allendale County. This site (38AL23) would eventually come to be known as Topper, although at the time that it was recorded it was not known that the site was quarry-related (Goodyear personal communication 2014). In 1981 a local landowner named David Topper noticed high concentrations of Allendale chert outcroppings on the site, and above the second alluvial terrace along the east bank of the Savannah River. In June of 1981, Topper brought this discovery to the attention of Dr. Albert Goodyear of the South Carolina Institute of Archaeology and Anthropology (SCIAA), who was interested in the outcropping’s potential for containing evidence of prehistoric use.
The quarry and associated escarpment, upon being shown to institute staff by David Topper, was designated the site number of 38AL139 (Goodyear and Charles 1984:80). According to Goodyear, the alluvial “terrace immediately adjacent to, and below the quarry had been previously entered into the South Carolina archaeological site file system as 38AL23” by Sutherland (Goodyear 1986:3). Although today, both 38AL23 and 38AL139 are essentially one site occupying two separate landforms, they were given two distinct site numbers. Figure A8-2 presents the dimensions of sites 38AL23 and 38AL139 alongside the distribution of auger test locations from the 1984 work. Because the material culture recovered from these sites “constitute in reality an archaeological whole, the name Topper was used to refer to both AL23 and AL139 collectively” (Goodyear 1986:3). When abundant Clovis artifacts were recovered on the Hillside and Hilltop portion of the Topper Site in 2004, the site number 38AL139 was dropped and the area subsumed under the designation 38AL23. However, because both sites were referred to as separate entities prior to 1998, both site numbers are used in the text of this chapter when discussing the contents of the assemblages recovered from the hilltop (38AL139), and floodplain Terrace (38AL23) during the first three seasons of fieldwork (1984-1986).

In 1983 and 1984, Tommy Charles, with the assistance of Albert C. Goodyear, conducted a survey of all exposed and eroded land surfaces in the western Allendale County, S.C. area, and identified 25 quarry related sites and 13 chert quarries (Goodyear and Charles 1984) Tables A8-1 through A8-20 present the of results of the 1984 Chert Survey and Auger Test on the Sandoz/Clariant/Achroma Property. These quarries typically consisted of exposed Allendale chert outcrops and associated scatters of lithic detachments. An example of one such quarry is presented in Figure A8-3. The results of the quarry survey were published as part of the University of South Carolina Research Manuscript Series (Goodyear and Charles 1984). The
initial survey strategy was opportunistic, and included the search for and collection of lithic materials from fire breaks, creeks, and all exposed eroded surfaces on the Sandoz property (Goodyear and Charles 1984: 8). If determined necessary, subsurface excavations were carried out with the aid of an 8-inch bucket auger, and were conducted in order to establish the depth of stratified lithic cultural materials (Goodyear and Charles 1984:13,80). The size of the auger allowed for the recovery of materials in 15cm levels without contamination from the margins of the hole (Goodyear and Charles 1984:13). Sites were auger tested in 15cm levels with sediments screened using 1/4 inch mesh. The section that follows presents the material culture by type and depth recovered from each quarry site tested from the study area. Appendix 9 presents the quantity and type of artifacts recovered from the 1984 site survey.

APPENDIX 10

RESULTS OF 1984 SURVEY AND LIST OF THE MATERIALS RECOVERED FROM AUGER TESTS (ATS) 1-5 AT THE TOPPER SITE (38AL23)
In July of 1983 and again in February of 1984 the chert survey led by Goodyear and Charles visited the Topper quarry (38AL139). No subsurface testing was carried out within the quarry at this time, as there was too much rock to “learn profitably about core reduction patterns through time in the midst of the source” (Goodyear and Charles 1984:80). However, the results of a surface survey did identify evidence of prehistoric quarrying activity at the Topper outcrop (38AL139). Figure A10-1 presents scatters of exposed chert from the chert outcrop along the hillside at the Topper Site (38AL139). Samples of chert from this locale were classified by Upchurch as a silicified grain-stone (Upchurch 1984). Initial investigations on the Terrace (38AL23) were carried out at Topper in 1984. An uncontrolled surface collection was conducted from a firebreak and an adjacent field. Prehistoric artifacts were recovered including temporally diagnostic pottery and non-diagnostic hafted bifaces (Figures A10-2-4) (Goodyear and Charles 1984). Ceramics recovered from this area include Deptford Linear Check Stamped, Deptford Check Stamped, Thom’s Creek Simple Stamped (dowel impressed) and an unknown sherd of curvilinear complicated stamped (Goodyear and Charles 1984:85). Hafted bifaces recovered from the site included a single triangular arrow point and possible Late Woodland stemmed point (Figure 4-6) (Goodyear and Charles 1984:85). Subsequent investigation included the placement of five auger tests, and a 1x2m test pit, the locations for which are presented in Figure A10-5. A list of the materials recovered from 1984 Auger Tests (ATs) 1-5 at Topper is presented in Tables A10-1-A10-5.

Auger Test (AT) 1 was placed in an area overlooking the secondary channel of the river. This test was conducted to determine if the site contained evidence of deeply buried, stratified cultural deposits. The auger test was excavated to a depth of 1.7m resulting in the recovery of flakes to a depth of 90cm, with only sporadic flakes occurring below this depth. According to
Goodyear and Charles “Given the relatively deep nature of the alluvial deposition and nearly a meter of artifactual deposit” additional subsurface excavation was planned and carried out on February 2, 1985 in the form of a single 1m x 2m unit, designated Test Pit 1, located on the floodplain terrace of the Savannah River (Goodyear 1986:3; Goodyear and Charles 1984:83). Excavation of this test pit is presented in Figure A10-5.

Artifacts from the Test Pit 1 recovered from 0-15cmbs include ceramic sherds (Refuge Simple Stamped, and rectilinear complicated stamped), chert flakes, and quartz cobble fragments. A dense ceramic zone was identified from 15-30cmbs including 57 sherds, of which 31 were Refuge Simple Stamped (Goodyear and Charles 1984). Pottery was absent below 30cm. Lithics recovered from these depths include two unidentifiable projectile point fragments, and retouched side and end scrapers. From 30-45cmbs there was a reduction in the number and distribution of artifacts. Lithics recovered included a single thermally altered projectile point fragment (stem). This zone was followed by a dense discrete layer of thermally altered flakes and artifacts from 45-60cmbs. Artifacts of note included five bifacial fragments, one core, and two utilized flakes, a projectile point tip, a side notched point, two scrapers, and two triangular point fragments. The scrapers and point fragments are illustrated in Figure A10-3 (c-f) (Goodyear and Charles 1984). In addition to these artifacts over 1,000 flakes and pieces of debitage were also recovered. Artifacts recovered from 60-80cmbs included a retouched end-scraper, a drill and 701 flakes and flake fragments (Goodyear and Charles 1984). Lithic materials were found to exhibit significant weathering from 70-80cmbs, and were pale white in color. From 80-90cmbs a weathered, stained early stage biface was recovered, and below that from 90-110cmbs flakes were recovered but trend occur in decreasing amounts with depth suggesting that they may have “been worked to these depths from above by bioturbation” (Goodyear and Charles 1984:90).
Auger Tests 2 and 3 were placed adjacent to one another and excavated in a location where the terrace meets the hillside slope. Artifacts recovered from these auger tests included a single ceramic sherd from AT2 (15-30cmbs), a chert end-scraper from AT2 (40-60cmbs), and a biface blank from 30-45cmbs in AT3. In addition to these artifacts, numerous flakes were also recovered. Interestingly, many flakes were recovered at great depth, and there was no indication of diminishing flake quantities with depth (Goodyear and Charles 1984:90-91). For example, from both tests a total of 29 flakes were recovered from 135-175cmbs, significantly deeper than the extent in depth of materials recovered from AT1. The results from these tests indicate that the northeastern end of the site has substantial depth (Goodyear and Charles 1984).

AT 4 was excavated approximately 60m south of ATs 2 and 3, and was conducted in order to gather more information about the “lateral depth of the site (Goodyear and Charles 1984:93). Unlike the prior auger tests, the artifact density was sparse in AT4. Accordingly, the extent of the sites deposits at this location was estimated at 1m in depth. The fifth and final auger test was excavated at the extreme southern end of the site. The top 75cm consisted of mottled clay and was devoid of artifacts leading the investigators to suggest that “cultural occupations on this portion of the terrace were probably light” (Goodyear and Charles 1984:93). Due to the stratigraphic integrity of cultural deposits encountered in ATs1-3, site 38AL23 was found to exhibit high potential for archaeological research and further scientific inquiry.

APPENDIX 11

MAPPED AND SCREEN ARTIFACTS FROM 1985 EXCAVATIONS AT THE TOPPER SITE (38AL23)
As a result of the archaeological discoveries from the preliminary investigations at Topper in 1984, further testing at the site was conducted from February 27\textsuperscript{th} to March 9\textsuperscript{th} 1985 and included the placement of seven 2m x 2m meter test units on the terrace. At this time, a grid system was established at the site including a permanent datum and elevation markers (Goodyear 1986). The datum was set at 100m ASL along the N200 E100 gridline. Units excavated in 1985 include N229 E110, N222 E108, N220 E087, N212 E130, N231 E091, N168 E090, and N204 E160.

Excavation commenced in 10cm arbitrary levels with all materials screened in 1/4\textsuperscript{th} inch screen mesh. All diagnostic artifacts were mapped \textit{in situ} and were recovered for further analysis, save for a few that were missed that turned up in the screen. Lithic debitage and flakes were not mapped unless associated with features, were over 2.5cm in diameter, or exhibited evidence for modification. Tables A11-1 to A11–3 present the results of the 1985 excavation. A total of seven 2m x2m test units were excavated at the Topper Site between March 1, and March 9, 1985, resulting in a total of 178 mapped artifacts and 349 artifacts from the screen, and seven features (Table A11-2-3).

Table A11-1 below lists the number of artifacts per unit by morphological type. Of the identified types, most are biface or flake tools, with core and production tools occurring in lower abundances. Table A11-2 presents the number of mapped artifacts by level for the 1985 field season, with items from the Paleoindian deposits represented in levels I-J. A total of 17 artifacts were mapped in situ from the Paleoindian deposits with most identified as bifaces or cores. One broken Paleoindian biface preform is illustrated in Figure A11-1. Table A11-3 lists the artifact catalogue for the 1985 field season which also provides provenience data on 68 of the mapped artifacts. This table also presents the mapped and unmapped artifacts recovered from the 1985
field season. In addition to the mapped artifacts from the seven test units excavated in 1985, a number of artifacts were missed and recovered in the screen. These items were larger than 2.5 cm but were mistakenly missed during excavation and turned up in the screen. The artifacts include 11 bifaces, 10 cores, 12 flake tools and three hammerstones from the presumed Paleoindian deposits (Table A11-3).

APPENDIX 12
NUMBER AND VERTICAL DISTRIBUTION OF MAPPED ARTIFACTS BY LEVEL
FOR THE 1985 FIELD EXCAVATION AND RESULTS OF 1986 EXCAVATION AT
THE TOPPER SITE (38AL23)
Appendix 12 shows the vertical distribution of artifacts by major artifact category for the 1985 field season. Based on the surface features on ceramics and flaking patterns on bifaces, the depths ranging from 0–30cmbs were interpreted as Woodland components, 30–70cmbs Archaic components, and 70–100cmbs Paleoindian components. Figures A12–1 to A12–7 present the vertical distribution of artifacts for each of the seven units. Artifacts from presumed Paleoindian deposits were recovered from all but one test unit (N229 E110) which was found to have an Archaic Palmer point approximately 50cmbs. Deposits in this unit were devoid of artifacts below 100cmbs. Other diagnostic artifacts recovered during the 1985 field include a Taylor point in N220 E087 at 56.5cmbs, and a Suwannee point in N231 E091 at 69cmbs. A total of ten bifaces and seven flake tools were mapped from possible Paleoindian deposits in the 1985 excavations this season providing an extensive culture chronology for the site.

Of the seven units excavated in 1985, all but one (N204 E160) unit was found to exhibit adequate stratigraphic integrity based on the vertical distribution of mapped artifacts. The profile map in Figure A12–1 (N231 E91) shows the stratigraphic separation between artifacts of different typologies, characterized by high concentrations of debitage at higher elevations and greater abundances of cores and bifaces in deeper deposits. Similarly, units N222 E108 and N229 E110 also demonstrate well-defined separation between the distributions of artifact types. However, because few artifacts diagnostic to a specific cultural period were identified, it was not possible to establish with certainty the exact time period that each assemblage reflects.

The 1985 excavations at Topper revealed discovered a total of eight features. These are labeled as F1–F8, and reflect the first eight of 121 features that have been identified at Topper through the 2012 field season. Features identified in 1985 include five lithic clusters, a possible
hearth and a Woodland burial urn. All feature fill was screened in 1/8\textsuperscript{th} inch screen mesh. A list of features for the 1985 field season is presented in Table A12–1.

Feature 1 is classified as a thermally altered lithic cluster from level 30–40cmbs in unit N222 E108. One stemmed projectile point and a biface were recovered in association with this feature but the artifact was not mapped. Other than these artifacts, Feature 1 consists of eight rocks which were drawn on the level records, but no additional provenience information was provided.

Feature 2 is described as a possible hearth located in unit N229 E110 beginning at 20cmbs and terminating at 30cmbs. Feature 2 contains approximately twenty Middle to Late Archaic (Allendale) thermally altered flakes that are associated with three bifaces and a hammerstone. The diagnostic artifacts were mapped and recorded. However, the associated flakes were only drawn on the plan-view map.

Feature 3 (Figure A12–8) is also a possible hearth and is described as consisting of a cluster of heat treated lithics recovered in proximity with dark, charred sediment. Feature 3 was identified from level C of unit N229 E110 (30–40cmbs). Artifacts recovered from Feature 3 include a stemmed point, six, biface preforms, one bifacial core a hammerstone and four core fragments.

Features 4 and 5 are lithic clusters identified in unit N220 E087. Feature 4 was identified in level F (50–60cmbs) and is described as an amorphous concentration of flakes in the southeastern section of the unit. A single Taylor projectile point was mapped and recovered in situ approximately 10cm to the east of the feature. However, the contents of Feature 4 were bagged and collected but were not mapped. As a result, the degree of spatial provenance is limited for this feature. Feature 5 is a cluster of flakes from level G (60–70cmbs) and is situated
in the center of the 2x2m unit. Elevations were provided for the artifacts associated with the feature but Northing and Easting data is absent. A single uniface was recorded within proximity to Feature 5. Feature 6 is a lithic cluster from level H (70–80cmbs) of unit N204 E160 and is situated in the southwest corner of the unit. The cluster ranges in depth from 70–75cmbs. Items from this feature were drawn in plan-view but were not recorded.

Feature 7 (Figure A12–9) is a Woodland period burial urn from unit N212 E130, and has been categorized as a Type I urn after McCann (1947) of the McDowell Phase that dates from 1350 A.D -1450 A.D (DePratter and Judge 1986). The feature was removed as a separate entity from the remainder of the unit and screened using 1/4\textsuperscript{th} inch screen mesh. The feature was intrusive into deeper Archaic deposits at the site. The vessel measured 24.5cm in height, 28cm in diameter at the rim, with surface treatment consisting of rectilinear complicated stamp/line block attributes. The vessel interior was smooth and burnished, and the exterior surface was found to display considerable surface sooting. Temper consisted of fine quartz sand. Objects recovered from the contents of the vessel included two isolated ceramic sherds, one projectile point, chert flakes, and bone. The function of the vessel is interpreted as serving in a secondary capacity as a burial urn due in part to the considerable wear found at the vessel base in addition to the exterior surface sooting along the upper portion of the vessel body; possible indirect evidence of cooking (Harmon 1989).

One important result of the 1985 excavation was the discovery of a potential Paleoindian presence at the site based on the recovery of 17 artifacts from levels I-J, the flaking patterns of bifaces recovered from these deposits, and the Suwannee point. Based on the success of the field season, it was determined that future investigations at the site were warranted based on these
discoveries, and that future research should focus on the exposure, identification, and dating of the Paleoindian deposits at the site.

801
Results of 1986 Excavations at the Topper Site (38AL23)

In 1986, excavation continued at Topper with the aid of funding through a grant provided by the National Geographic Society. An additional 18 1x1 meter units were excavated this season (in two adjacent 3x3m blocks revealing an assortment of lithic materials and debitage spanning nearly 10,000 years of culture history in the area (Figures A12–10). The excavation blocks were labeled numerically as Block I and II, and the nine 1m units within each block were assigned alphabetic labels ranging from A to I (Figure A12–10). The blocks were situated on the floodplain terrace approximately 30m east of the river bank. Block I was placed to the immediate west of Block II. The excavation employed arbitrary levels, with the first level (A) excavated to 10cmbs and all succeeding levels removed in arbitrary 5cm increments (Goodyear 1986). A total of seven levels were excavated and labeled A-G accordingly. All excavations within these blocks were hand troweled to sterile subsoil with all fill dry screened through 1/4\textsuperscript{th} inch screen mesh. A large contiguous area was selected for excavation in order to gather data on intra-site spatial distributions (Goodyear 1986:2).

After the 1986 field season, all materials recovered from the excavation were taken to SCIAA for subsequent lithic and ceramic analysis. A lithic analysis of units A and B (two units) from block I, levels A-G was conducted as part of a senior honors thesis in 1989 (Carambelas 1989). The goal of this study was to determine onsite lithic reduction patterns through time at the site and to assess quarry behavior with regard to the type of tool stone selected for subsequent reduction. A total of 4,743 lithic items were recovered and analyzed from the two 1x1m units. This analysis resulted in the recovery of eleven formalized tools, and a substantial quantity of lithic debitage (Table A-1). Formalized tools recovered from this excavation include an end scraper, two unifaces, one core, and three projectile points from the plow-zone; one biface and
one uniface from the Woodland deposits; one projectile point from the Late Archaic deposits; and one biface from the Paleoindian deposits (Table A12–2).

While only a single biface was recovered from the Paleoindian deposits, the high abundance of biface thinning flakes from these levels (n = 1,630 or 47.74% of the assemblage) is indication of intensive lithic reduction in this area of the site for the time period. In fact, bifacial thinning flakes were the dominant debitage category consisting of 82% of all debitage types (Carambelas 1989:16). A visual inspection of these materials lead investigators to conclude that this area of the site served as a biface reduction locus, and that later Woodland and Archaic peoples partially reduced biface cores or blanks and transported them to the area of the hill-slope for further reduction (Carambelas 1989:17). The small quantity of Middle (Morrow Mountain) and Early Archaic projectile point performs from these units (N=4) suggests that biface reduction terminated early along the biface reduction continuum.

All debitage and tools from the selected units of the 1986 excavations were examined by condition; presumed raw material type/source area (i.e., upland cortex chert or or river chert) in order to assess material selection behavior. The results of this analysis found that upland cortex accounts for 87–100 percent of the debitage in levels B-G, and 68% of the debitage in level A (plow-zone) (Carambelas 1989) (Table A12–3). Based on the relative frequencies of upland and river cobble chert types among the flakes recovered from the excavation, upland chert was preferentially selected over river chert for tool-stone production. Although a total of 18 units were excavated during the 1986 field season, only the two units of the analyzed lithic materials discussed above have thus far been systematically documented.

In addition to the lithic materials, 3,250 ceramic artifacts were recovered from the 1984–1986 excavations at Topper. In 1985 and 1986 analyses were undertaken to determine the
temporal chronological placement of ceramic types at Topper and their vertical and horizontal
distribution in excavated areas of the site (Harmon 1986; Mulcahay 1985). A 1985 analysis of
the distribution of ceramics from four test pits (N212 E130, N229 E110, N231 E091, N188
E090) was carried out, with two units (N231 E091, N229 E110) producing high quantities of
sherdlettes in the plowzone; indicating that the area had been subjected to plowing/cultivation at
some point following the deposition of the pottery (Mulcahay 1985).

A subsequent study in 1986 was conducted, and examined the ceramic assemblage from
Blocks I and II and from four 2x2m test pits (N231 E091, N188 E090, N220 E087, N204 E160),
two of which had undergone analysis in 1985 (Harmon 1986). This analysis resulted in the
identification of 397 pieces of ceramic prehistoric pottery. The results of this analysis are
presented in Tables A12–4–A-6 which show the quantity of ceramic sherds by type recovered
from each excavation.

Figure A10–4 presents some of the most common examples of ceramic items recovered
from surface contexts at Topper. Most ceramic materials were recovered from levels A-C within
the units examined in 1985 and 1986 (0–30cmbs), and the results of the study show that most
ceramic materials from the units examined consist of Refuge (n=93), Deptford (n=179), and
Savannah types series (n=95), and are in a logical stratification. Types occurring with less
frequency include Cape Fear (n=20), and clay/grog (n=10). The occurrence of Stallings and
Thom’s Creek phase ceramics is rare at Topper which is interesting given that such phases are
documented at other sites in the lower Savannah River Valley (Anderson 1975; Hanson et al.
1981; Stoltman 1964 and others). The abundance of ceramic items recovered at Topper implies
that the site was intensively inhabited during the Woodland and Mississippian periods (see
Appendix 1).
Based on the preliminary lithic and ceramic investigations resulting from the 1984–1986 field season, a cultural sequence at Topper was developed (Goodyear 1986:4). This sequence includes a Mississippian occupation from ca. 0–10 centimeters below surface consisting of both ceramic and lithic materials. Ceramics include types from the Savannah Phase; Savannah Fine Cord-marked, Savannah Check Stamped, Savannah Complicated Stamped, and Savannah Burnished (Mulcahey 1985; Harmon n.d.). According to Goodyear, “most of the Savannah Ware appears based on rims and decorations, to be pre 15th century (Goodyear 1986:4). Lithics recovered from the Mississippian component include small triangular projectile points.

A Woodland component was identified from ca. 20–35cmbs within the excavation block, and consists of Deptford Simple Stamped, Checked Stamped, and Bold Checked Stamped and Linear Check Stamped pottery. These wares indicate a date range extending from 500 BC-A.D. 500 and are consistent with the Early to Middle Woodland Periods. The Early Woodland period is marked by the occurrence of Refuge Simple Stamped pottery and Yadkin projectile points. Interestingly, Thoms Creek and Stallings Island fiber tempered pottery were absent at Topper in these units.

In 1986, a Middle to Late Archaic component was identified at Topper from ca. 30–50cmbs. Although ceramics are lacking from these deposits, a substantial thermally altered chert horizon was identified and consisted of large quantities of heat treated bifaces and concentrations of burned rock. The burned rock could indicate the presence of cooking activities on site. However, no charcoal was present in sufficient quantities that would allow for radiocarbon dating of the contents of the Archaic biface layer. Although bifaces were found to be variable in form, according to Goodyear, they appear to be expanded stem or corner notched forms (Goodyear 1986:5). A small sample of the points recovered during this season appear to be what
have commonly been referred to as MALA points (Sassaman 1985) and since renamed Allendale (Whatley 2002:13). These points predominantly have a biconvex cross section, relatively thick blade forms and symmetrical blade margins. Examples of Allendale points recovered at Topper are presented in A35–13–A35–14. Based on stratigraphic association, these artifacts would appear to date within a range of 5,000–6,000 cal yr B.P.

Below the Allendale zone, an Early Archaic component was identified at Topper between ca. 55–80cmbs. This component consists of “a side-notched Early Archaic deposit characterized by highly weathered chert” (Goodyear 1986:9). Thermally altered lithic bifaces are absent from these depths, and instead the lithic materials appear to be more weathered than materials from the overlying sediments. Also absent are the concentrations of fire cracked rock that were plentiful in the Allendale levels (Goodyear 1986). Artifacts consistently found from the Early Archaic zone include unifaces and diagnostic Taylor projectile points. As of the 1986 field season, two Taylor points had been mapped in situ. One Taylor point was recovered at 69cmbs within the block excavation and the second was recovered from 78cmbs. Based on stratigraphic association and degree of weathering, these points were initially presumed to date approximately 10,000 cal yr B.P (Goodyear 1986), however more recent studies place these dates approximately 11,500–10,000 cal yr B.P. (Anderson and Sassaman 2996; Michie 1996).

Non diagnostic unifaces and bifaces were recovered from 70–100cmbs and are thought to reflect a Paleoindian presence at the site. Because no Clovis projectile points or blades were found during the 1986 excavation, the presence of a Paleoindian occupation at the site could not be definitively verified. However, the discovery of numerous non diagnostic bifaces, unifaces, and utilized tools beneath strata containing the side notched Taylor points suggested a likely earlier, Dalton or Clovis occupation at the site. Such deposits were buried at the base of C-
horizon sands resulting from colluvial slope-wash originating from the hill-slope (Goodyear 2007). Although no artifacts were recovered below the Paleoindian levels in 1986, a notable amount of flakes were recovered below these deposits during the initial season of fieldwork. The 1984 auger tests resulted in the discovery of no fewer than 29 flakes between 120 and 175cmbs in auger tests two and three either indicating great time depth for the site or the potential for assemblage disturbance via bioturbation. After the 1986 field season, excavations at Topper ceased until the summer of 1998. Between 1992 and 1997 archaeological investigations on the Clariant property were focused on the nearby Big Pine Tree Site, an Archaic and Paleoindian lithic workstation approximately 2km north of Topper (Russell 2015; Waters et al. 2007).
Figure A12–10B

Map showing the 18 1x1m units excavated in 1986. These comprise two adjacent 3x3 block excavations (Block I and Block II). 2x2m Units N222 E108 and N229 E110 were excavated in 1985. Shaded 1x1m units A and B of Block I represent units selected for ceramic and lithic analysis by Carambelas (1989).

APPENDIX 13

PERCENTAGE OF ARTIFACTS MISSED FOR EACH LEVEL AND RECOVERED FROM SCREEN
An issue concerning site recovery protocol involves the percentage rate of interobserver error in artifact recovery. According to procedure, all items 2.5cm or greater are three dimensionally mapped within the site grid. If an item smaller than 2.5 cm was deemed to be of cultural origin or appears to take the form of chipped stone debris, such materials were also mapped. However, the potential exists that some items that meet this size criteria (>2.5cm) were missed in the field and subsequently placed in the screen. To determine the rate of error in the mapping protocol, and to ascertain if the spatial array of artifacts has been preserved, all materials from the screen were subjected to a size grade analysis. Accordingly, the combined weight of all screened and plotted items greater than 2.5cm was recorded for each level, the total for which comprises 100% of the materials per level for the given size grade. By comparing the percentage of 2.5inch artifact screen weight by the percentage of 2.5 inch plotted artifact weight, it was possible to determine the error/artifact recovery rate for each level by stratigraphic deposit. The results of this analysis are presented here in Appendix 13 and in Table A13-1. Based on the analysis, the average percentage of flaking debris greater than 2.5cm that was missed in the field ranges from a high of 8.6% for the Clovis deposits to a low of 4.07% for the Pleistocene Terrace. On average, 4.93% of chipped stone tools and debris from the Pleistocene Sands were missed and not mapped in the field. These findings imply that at least a small portion of the spatial representation of larger artifacts from the site is missing (i.e. was/were not mapped) and is therefore inaccurate. Although the percentages are not high, the presence of artifacts larger than 2.5 cm from the screen illustrates one shortcoming from of the current approach the study.
Appendix 13 presents the percentage of artifacts, debitage, and lithic materials by level that are larger than 2.5cm and that were missed during level excavation and mistakenly placed in the ¼ inch screen. The appendix includes data on 676 levels of excavated materials. A total of 349 of these levels derive from the Pleistocene Terrace while the remaining 327 levels are from the Holocene and Pleistocene Sands. The Appendix includes eight columns. Column one provides the level provenience information followed by level depth in column two. Columns three through six provide data on the percentage weight of different lithic categories: 3; the sum weight of all materials from the entire level, 4; the sum weight of 2 ½ in or greater cortical materials recovered from the screen, 5; the sum weight of 2 ½ in or greater quartz materials recovered from the screen, and 6; sum weight of 2 ½ in or greater flake materials recovered from the screen. Column seven presents the combined weight of cortical, quartz and flake materials for the 2.5in size grade that were recovered from the screen. Column eight presents the percentage of material from each level that was not mapped, and subsequently placed in the screen. A total of 23 levels were found to have had greater than 25% of the 2.5 inch level sum placed in the screen. Of these, 21 levels were from the Holocene Sands and excavated prior to 2004. Figure A13-1 presents examples of lithic items greater than 2.5cm for comparison.

APPENDIX 14

BACKHOE TRENCH EXCAVATIONS AT THE TOPPER SITE (38AL23)
The use of a backhoe was also occasionally warranted at Topper to test for the presence of cultural materials, and to examine the geostratigraphy of the site. As of 2012, a total of 20 backhoe trenches (BHT) have been excavated at Topper. Figure 4-13 presents the location of all backhoe trenches relative to unit excavation through the 2005 field season. A list of all Backhoe Trenches is provided in Appendix 14. The majority of the trenches were excavated in 1999 and 2000 in conjunction with the geoarchaeological investigations by Waters et al. (2009) in order to investigate the stratigraphic profile of the Pleistocene deposits at the site and to obtain materials suitable for radiometric or OSL dating. No backhoe trenches have been excavated onsite since 2005. A total of 18 of the 20 backhoe trenches were excavated on the floodplain terrace, while the remaining two trenches were situated on the Topper hillside and hilltop respectively. When backhoe trenches were opened, a small sample of materials fill from each trench was screened through ¼ inch screen mesh and diagnostic artifacts were subsequently bagged and labeled.

APPENDIX 15

MAPPED ARTIFACTS FROM THE TOPPER SITE (38AL23)
Results of 1998 Field Season

The 1998 investigations resulted in the discovery of an abundance of lithic material from the manufacture of chipped stone tools. A list of the recovered mapped items by type for the 1998 field excavation is provided in Appendix 15. Based on the available level records, the results of the excavation produced a total of 68 mapped formalized tools from the Holocene and Paleoindian deposits including 11 cores, 31 biface tools, 22 flake tools, and four production tools (Table A15-1). In addition to these artifacts, 113 informal tools and flakes were also mapped. The 1998 excavations at Topper resulted in the discovery of lithic tools of Archaic and probable Clovis age. A Woodland component was also identified based on the presence of Refuge and Deptford pottery.

Artifacts recovered from the Archaic deposits include Allendale and Morrow Mountain points, bifaces (n=21), blades (n=4), cores (n=6), unifaces and scrapers (n=5), and hammerstones (n=3) (Table A15-2). Materials from the MALA horizon (40-60cmbs) consistently display evidence for thermal alteration. An Early Archaic component was identified in unit N244 E106 based on the discovery of a Taylor side notched point at 70cmbs. A fluted biface was recovered from 81cmbs in unit N244 E106 providing good indication of intact stratified deposits for this unit. Artifacts recovered from the Paleoindian deposits included bifaces (n=2), fluted performs (n=1), scrapers (n=1), cores (n=2), and utilized flakes (n=3) (Appendix A15-2). Of note was the discovery of large prismatic blades and cores found in association with the bifaces from the Paleoindian stratum in levels 7-10 from unit N244 E106 (Sain 2012).

PS = Pleistocene Sands
Results of 1999 Field Season

A total of 430 artifacts and lithic items were mapped from these units over the course of the 1999 field season in addition to the excavation of four backhoe trenches (BHT1-4) and 18 features (Table A15-3). According to the record levels presented in appendix A15-3, lithic artifacts recorded in 1999 include 30 core tools, 36 bifaces, 63 flake tools, two hammerstones, 299 flakes and flake fragments. Many of these items were recovered from features. Of the 430 items mapped this field season, 122 derive from pre Clovis deposits. Lithic specimens such as rocks that were not considered artifacts but that were larger than 2.5cm were also mapped in situ, and were classified as “items” as opposed to artifacts. The provenience information for such specimens was recorded on the level bag but was not always recorded or drawn in the level records. In addition to the mapped artifacts, a total 77 artifacts were recovered from the screen, and were documented in the artifact logs. These artifacts are presented by type in Appendix 15, and include 16 bifaces and projectile points, 14 blades, 15 unifaces and scrapers, 10 cores, five flake tools, and two hammerstones in addition to a number of rocks, and debitage.

A Paleoindian horizon was identified from 90-110cmbs in the 48 square meter primary block excavation (Goodyear 1999:9). Of 276 mapped artifacts from this block excavation, a total of 45 were recovered from the presumed Paleoindian deposits. An additional 64 lithic items were mapped and recovered from the Paleoindian deposits but were not given artifact numbers. Most of the Paleoindian tools from the 48sq, meter block included utilized flakes, unifaces, and scrapers, with other artifact forms such as cores and bifaces occurring in lesser abundances.

A total of 48 of the 122 mapped pre Clovis artifacts recovered in 1999 were recovered from the Pleistocene Terrace in the 48sqm block. However, these artifacts differed in morphology when compared with the items recovered from units excavated to the North at the
base of the hill slope the prior field season. Most artifacts recovered were identified as either small flake tools (n=6), broken quartz pebbles/tools (n=72), or unspecified rocks or debitage (n=34).

A 4m x2m block was excavated to a depth of 170cmbs in units N242 E130 and N242 E132. Excavation carried out at this location resulted in the mapping and recovery of 124 artifacts and lithic items (Table A15-3). Among the artifacts identified are 23 Woodland and Archaic period artifacts, nine Paleoindian tools, and 92 artifacts from the Pleistocene Sands. Formal tools from the 4m x2m block include nine cores, nine bifaces, 16 flake tools, one hammerstone in addition to 89 unspecified artifacts.

At least two distinct lithic working surfaces were identified in the 1999 4m x2m block and include an Archaic biface cache (labeled as F48) situated between 98.30-98.40m and a linear distribution of lithic artifacts and debris situated at the base of the Pleistocene Sands from elevation of 96.90-97.05m. In the Pleistocene Sands of unit N242 E132, a pre Clovis lithic cluster (labeled as F49) was observed in close proximity with Feature 23 which had been previously identified the prior field season. Excavation of Feature 49 revealed a number lithic cobbles and small flake tools. Interestingly, a high percentage of the lithic cobbles from this Feature were relatively large and greater than 10cm in diameter. In addition to Feature 49, other artifacts recovered from the Pleistocene Sands in unit N242 E132 include flake tools, an end scraper, and a number of small blade-like flakes that have square cross sections and are similar in morphology to burins and burin spalls (Goodyear 1999:9).

In addition to the 4x2m block excavation, two additional 2m x 2m units were excavated at the northern end of the Topper Site in 1999. These units include N268E132 and N282 E132. A total of twenty two artifacts were recovered in unit N268E132 and include three core tools, 11
bifaces, a flake tool, and seven additional flakes and flake fragments. The bifaces were most prevalent from the Archaic and Paleoindian levels. Flakes, flake tools, and cores were recovered from the Pleistocene Sands of unit N268 E132. An examination of the contents of unit N282 E132 revealed fewer artifacts (n=8). Of these, five were recovered from the Paleoindian deposits and include a uniface, blade core, scraper, and bladelet. A single burin spall was recovered from the Pleistocene Sands of unit N282 E132.

Results of 2000 Field Season

A 4m x 8m meter block excavation was opened in 2000 extending from N242 to N244 along the E128 to E136 grid lines. A second 2x4 meter block excavation opened along the N244 grid line from E146 to E150 (Goodyear 2000). A total of 505 lithic items were mapped from the block excavations of the 2000 Field season, and at least 46 items were recovered from the screen over the course of the 2000 field season (Table A15-5). Table A15-6 presents the chronological distribution of mapped artifacts by tool type recovered in 2000. Woodland Period artifacts consist largely of stemmed projectile points or bifaces (n=5) and were frequently found in association with broken ceramics. Other mapped artifacts from the Woodland component include a blade, a flake tool, and 15 non-specified flakes and flake fragments. The Archaic and Paleoindian deposits are characterized by an increase in the frequency of bifaces (n=11), blades (n=9), cores (n=5), and flake tools (n=5). Most of the bifaces are preforms or are early stage blanks as opposed to finished points. The most frequent tool types from the pre Clovis deposits were utilized flakes and flakes tools, cores, and blades. A high percentage of mapped items from these deposits also consisted of broken chert and quartz cobbles.

As is evident from the vertical distribution of artifacts in Table A15-6, the base of the Holocene colluvium (97.80-98.10m) is dominated by bifaces (n=9), blades and flake tools (n=13), cores (n=5) and hammerstones (n=3). Although temporally non-diagnostic, these artifacts are frequently associated with Clovis chipped stone tool production. Below the Clovis deposits there is an increase in the amount of flake tools and scrapers (n=11), as well as small pebble/cobble tools (n=4). In addition to these artifacts, a total of 164 additional artifacts were mapped including rocks, cobbles, boulders, flakes and flake fragments, burins, burin spalls, small
utilized chert flakes with striking platforms and bulbs, unifacially retouched flakes, and small blades and bladelets (Goodyear 2000).

A total of 296 artifacts were mapped from units N244 E146, and N244 E148 (A15-5) which comprises the 2000 2x4m block. Of the artifacts recovered, 25 derive from the Woodland deposits, 25 were mapped from the Archaic deposits, 86 from the Paleoindian levels and 160 were recovered from the Pleistocene Sands between elevations of 140 and 220cmbs. These findings indicate a substantial deposit quantity of lithic materials came from the Pleistocene Sands in this area.

Very few formal tools were recovered from the Holocene deposits of the 2000 2x4m block. A single Yadkin point was recovered from the Woodland deposits and a MALA point from the Archaic levels. The MALA point and associated flakes from the Holocene deposits were used to distinguish a Middle to Late Archaic lithic reduction zone in this area of the site. By contrast, the density of formalized tools was found to increase in the Paleoindian deposits. Formalized Paleoindian artifacts include three biface fragments, three flake tools, two cores, a scraper, and two Paleoindian hammerstones. A biface perform fragment was recovered at 95cmbs and is considered to be Paleoindian in origin. Additional artifacts from the Paleoindian deposits consist of a cluster of rocks, flakes and small blades that was labeled as Feature 62 and is presented in plan-view in Appendices 18 and 23. Most lithic artifacts recovered from the pre Clovis deposits in the 2000 2x4m block were preliminarily identified as flakes, debitage, or chert pebbles/cobbles.

Results of 2001 Field Season

The results of the 2001 Field season at the Topper Site resulted in the mapping and recovery of 436 lithic items and artifacts, of which 297 were recorded in the level records. These artifacts were recovered from three excavation blocks including a 5x10m block, a 4x6m block and 10 1x2m units presented in Appendix 22. The distribution of artifacts by unit and by type are presented in Table A15-7. In addition to the mapped items, 110 artifacts were recovered from the screen and are presented in Appendix 16. Excavations carried out in units N240 E128-E132 produced a dense layer of Clovis and pre Clovis artifacts resulting in the recovery of 156 mapped items or approximately 35% of all materials plotted from the field season (Table A15-7). From unit N240 E132, 73 artifacts were mapped from the Clovis deposits and consist of bifaces, blades, and utilized flakes. An additional 108 lithic items were mapped from the pre Clovis levels of units N240 E128-E132 consisting of small flakes, cores, utilized pebbles and bend breaks. In total, the results of the entire 2001 5x10m block pre Clovis excavation produced a total of 19 tools (two blades, four cores, 11 flake tools), in addition to 164 flakes, flake fragments, cobbles, and boulders. A total of four lithic clusters were also identified below the Clovis contexts (Appendix 23). These clusters were subsequently given feature numbers and include Features 77, 80, 82, and 83. The pre Clovis features were well defined and typically consisted of numerous lithic items that under preliminary observation, exhibit attributes consistent with chipped stone debris (Goodyear 2001). A total of 60 lithic items were mapped and recovered from Feature 77 which extends from 150-155cmbd (97.25-97.20M) making it one of the largest pre Clovis lithic clusters identified at the site to date (see Appendix 18).

Excavations were conducted along the southern, eastern, and western perimeter of the 5x10m block excavation were conducted to serve as a baulk that would prevent collapse of the
sandy profile wall as excavation progressed deeper. In total, ten 1x2m units were placed and were excavated to a depth of 97.80m (approximately 110cmbd) to the base of the Clovis deposits. A total of 17 artifacts were mapped from these units and include a single MALA point, and 10 scrapers, one biface preform, and one utilized flake from the Clovis deposits. To the west of the 1x2m units, a 4x6 block was excavated to 97.00m or 113cmbd, the base of the Clovis zone. Excavation below the Clovis zone was not undertaken in this block. A total of 117 lithic items were mapped, including four features (F 73, 75, 78, and 79). Features 73 and 79 are Early Archaic/Paleoindian lithic workstations consisting of chert scrapers, denticulates, blades, cores, hammerstones, and flakes. The interpretation that this area served as a lithic workstation is based primarily on the diversity of tool forms and associated manufacture debris recovered in close proximity.

</table>
Results of 2002 Field Season

Excavations at the Topper site in 2001 resulted in the recovery of 828 mapped lithic items, the most of any season up to this date. The distribution of these artifacts by unit and by type is presented in Table A15-8. During the field season a new 5m x 9m excavation block was opened up immediately to the East of the 2000 4m x 8m block. This excavation was situated along the N242-N246 and E136-E144 grid lines, and was taken to the top of the Pleistocene terrace at 97.35m.

The distribution of mapped artifacts from the 2002 5m x 9m block excavation is presented in Table A15-8. Biface (38), Core (81), and flake tools (9130) make up the most dominant tool types recovered from the 5m x 9m block. Table A15-9 presents the distribution of lithic tool types by culture chronology. The results of the 5m x 9m block investigation revealed 1; a minor Woodland and Mississippian component consisting of 1; pottery (n=3), shell (n=2), and bifaces (n=8); 2; a substantial Middle to Late Archaic component from 35-50cmbs dominated by numerous hafted bifaces (n=48), 3; a Paleoindian component approximately 1 meter below the ground surface consisting of numerous unifacial and un-diagnostic bifacial tools from Pleistocene age sediments (n=23) and including a single feature (F85);, and 4; a possible pre Clovis assemblage stratigraphically separated from the Paleoindian deposits and consisting of spatially clustered concentrations of chert cobbles and pebbles and associated flake tools within 25cm of the top of the Pleistocene Terrace.

The Archaic levels are dominated by MALA and Early archaic Archaic bifaces and projectile point preforms including Allendale and Taylor types (27). Cores (20) and scrapers (14) were also frequently encountered. Numerous pieces of thermally altered debitage document were
found in the upper levels of the Archaic zone with a transition to more weathered chert flakes from the Early Archaic levels.

The Paleoindian deposits from the 5m x 9m block are represented by the occurrence of 104 three dimensionally mapped artifacts and 36 additional artifacts recovered from the screen (Table A15-9 and Appendix 16). The Paleoindian deposits in this area of the site are identified by an increase in the number of transverse biface thinning flakes, blades, and Clovis fluted preforms and a reduction in flake tools and scrapers. A single feature, feature, F85, was identified from the Middle Paleoindian deposits from the 5m x 9m block excavation at an elevation of 98.10m and was assigned the feature number 85. This feature was located in unit N244 E136 and contained bifaces (3), unifaces (6), cores (2), burned chert fragments (7), a single utilized flake, blade, and chert cobble. The plan-view map in Figure A23-12 of Appendix 23 shows the spatial distribution of Feature 85. Below this feature, colluvial and alluvial sediments were predominantly sterile of lithic materials until reaching elevation 97.50m where putative artifacts of pre Clovis origin were encountered.

The pre Clovis deposits from the 5m x 9m block excavation are characterized as spatially clustered associations of chert cobbles, cores, and microlithic tools including small blades, flake tools and bend breaks. The lack of bifaces distinguishes the pre Clovis zone from the overlying Clovis and Archaic materials. The pre Clovis lithic deposits in this area of the site range in depth from 97.75m to 97.10m to the contact with the Pleistocene Terrace. In total, 354 mapped items and seven screen items were recovered from the 5m x 9m pre Clovis deposits and include flake tools (n=49), cores (n=46), scrapers (n=28), flakes (n=22), bend breaks (n=18), and blades (n=6). The majority of these items were preliminarily identified in the field as chert cobbles or pebbles as described above.
Three features were identified from the pre Clovis zone of the 2002 5m x 9m block excavation, (and are presented in Appendices 18, 23). Feature 86 is a cluster of rocks in the northeast quad of N244 E142 at an elevation of 97.70m. Feature 86 includes 13 rocks, a possible anvil stone, a quartz hammerstone, and two chert cobbles that refit. No diagnostic artifacts were recovered with Feature 86. To the south and west of Feature 86, a chert cluster was identified beginning at an elevation of 97.55m in unit N244 E142. This Feature was designated Feature 88 and consists of over 60 mapped items including chert and quartz cobbles (n=29), flake tools (n=12), bend breaks (n=8), cores (n=5), flakes (n=5), and hammerstones (n=3). The feature was restricted to an area approximately 60cm N/S and 40cm E/W. The third Feature feature (F87) identified from the pre Clovis deposits in 2002 includes a cluster of chert cobbles and tools at an elevation ranging from 97.50-97.36m in unit N244 E138. A total of 67 lithic items were mapped associated with this feature and include chert and quartz cobbles (45), chert flake tools (13), chert cores (6), bend breaks (2), and quartz hammerstones (2). By the completion of the field season, excavation in the 5m x 9m block had reached within 15cm of the top of the Pleistocene Terrace surface.

Apart from the 5m x 9m block excavation, two additional block excavations were carried out in 2002. These include a 4x4m block from N267-E134 to N269 E136 and a 4x6m block from N284 E134 to N286 E138. A substantial Clovis lithic workstation was also encountered in both of these excavation blocks. The Clovis artifacts were identified based on the co-occurrence of outré passé' flakes recovered in association with the base of a single fluted point. As such, the lithic deposits were interpreted as a Clovis workstation where biface and blades were produced and subsequently discarded after use. The N267 E134 block produced 51 mapped artifacts, 31 of which were classified as bifaces. A single core tool and 14 flake tools
were also identified. A total of 118 artifacts were mapped from the N284 E134 block. These include cores (929), bifaces (17), flake tools (32) and a single hammertone.

In the N267 E134 block, excavation below the Clovis zone commenced as a 2m x 2m unit (N267 E135) to the top of the Pleistocene Terrace. The purpose of this excavation was to test the proposition that a pre-Clovis occupation was present north of the primary 5m x 9m block excavation, and upstream from all other identified materials of such age (Goodyear 2003). Four square meters of sediments were excavated down to the Pleistocene Terrace in 11 10cm levels, with little evidence for artifact bearing deposits below the Clovis levels. A total of 11 items were mapped and consist of rocks, small flakes, a possible core fragment. This distribution contrasts markedly with the high artifact densities encountered at the base of the Pleistocene Sands in the primary block excavation ca. 20 m to the south.

Results of 2003 Field Season

Three block excavations were carried out during Archaeological investigations at the Topper Site in 2003. These include the 5m x 9m block excavation begun in 2002, a new 6m x 6m block excavation and a series of 2x3m units along the northern perimeter of the site (illustrated in Appendix 22). The provenience and artifact classification for all mapped artifacts recovered during the 2003 field season is presented in Table A15-10. In total, 592 lithic items were mapped in 2003. This number includes 383 mapped artifacts in addition to 209 lithic items that were mapped, labeled and bagged, but were not recorded in the level records. A total of 12 artifacts were recovered from the screen (Appendix 16).

In 2003, excavation continued in four of the 2m x 2m units from the 5m x 9m block excavation begun the prior year. These units include N242 E140, N242 E142, N244 E140, and N244 E142. All materials excavated from these units in 2003 were from pre Clovis deposits. A total of 146 pre Clovis artifacts were mapped from these units in 2003 revealing additional cobble clusters and putative stone tools. While nearly 50% of these pieces (72) were identified as chert cobbles or pebbles, the remaining lithics were preliminarily classified as bend breaks (n=13), hammerstones (n=11), cores (n=18), flake tools (n=18), flakes (n=6), scrapers (n=5) or small blades (n=3) (Table A15-10). Unit N244E142 was found to have the highest abundance of potential tools with 27 items mapped from the pre Clovis contexts. These included nine flake tools, two core tools, three bend breaks, and four production tools.

Of note, six retouched or utilized chert tools were recovered from the 2003 5m x 9m block, and at least two were found in close proximity to a large chert boulder resting at the contact of the Pleistocene Terrace. These items, according to Goodyear (2005) are irrefutable evidence of human agency in the production of chipped stone tools.
A single feature was identified in 2003; a lithic cluster assigned Feature 90 and composed of chert cobbles (n=9), flakes, a utilized flake (n=1), cores (n=2), a single bend break (n=1), and a quartz hammerstone fragment (n=1) (Appendix 18). Feature 90 was encountered resting near the contact with the Pleistocene Terrace surface at elevation 97.30-97.25m at the coordinate of N243 E141. A profile and plan view map of the 2003 5m x 9m excavation presents the spatial distribution of mapped artifacts associated with Feature 90 (A23-13). In addition to Feature 90, a second lithic cluster was encountered in unit N244 E142 between 97.30-97.25m that was not assigned a feature number. This association cluster consists of 24 lithic items including chert scrapers (n=2), utilized flakes (n=2), battered quartz (n=1), chert cobbles (n=17), chert flakes (n=1), and an anvil. Two of the chert flakes associated with this lithic cluster were found to refit to scars on the surface of the adjacent boulder classified as an anvil (Figure 4-27). A search of the level records revealed that this association was not assigned a feature number.

The 6m x 6m block excavation was placed at the N270 E152 grid line and extending to N276 E158. The goal of this excavation was to determine if there are similar patterns in the distribution of pre Clovis materials along the northern perimeter of the site. Excavation began at ground surface (ca. 99.30m) and continued to the base of the Clovis deposits. Clovis artifacts encountered in this block are interpreted, based on observation, to represent early stage lithic reduction and core preparation, as the majority of lithic cobbles were relatively large and still retain cortex (Goodyear 2003). Although than 700 individual lithic items were identified and recovered from the Paleoindian levels in this block, less than 200 were actually three dimensionally plotted. Among the notable artifacts mapped from these deposits included 22 bifaces, 14 flake tools, 11 blades, 26 cores, 4 hammerstones, and 17 scrapers.
Immediately Beneath the Clovis deposits, the excavation area was condensed reduced to a 4m x 5m block (N272 E152 to N276 E157) and excavation continued through a “red” paleosol (Goodyear 2005:4). Other than quartz pebbles and “chemically weathered cortical material”, the paleosol was sterile of archaeological materials within the 20 square meters indicating an absence of human occupation between the Clovis and reported pre Clovis assemblage from the Pleistocene Sands (Goodyear 2005:5). Below the paleosol, excavation continued as a 2m x 4m unit (N274 E154) from 98.25m through white Pleistocene age alluvial sands to the top of the Terrace Pleistocene Terrace at 97.00m. From the Pleistocene Sands, small flakes were recovered from the screen, some of which had bend break fractures consistent with those found in the primary 5m x 9m block (N242-N246 and E136-E144) excavated to the south in 2002-2003. At 97.35m a spatially concentrated chert cluster containing seven lithic items was revealed but was not given a feature number. This cluster was similar in form to those identified from the 2002 5m x 9m excavation (Goodyear 2005). No other artifacts larger than 2.5cm were encountered or mapped from the pre Clovis deposits in this unit.

To the north of the 6m x 6m block excavation, a series of units were excavated along the N284 gridline and include 5 2m x 2m units placed extending from N284 E132 to N288 E136. Excavation began at 98.50m and concluded at the base of the Holocene Colluvium at 97.30m. Of the 203 artifacts mapped from this block, cultural materials associated with Woodland (25) and Archaic (59) periods were recovered and mapped from the Holocene deposits. A possible Paleoindian assemblage was identified from the 5 2m x 2m unit excavations. Artifacts mapped and recovered from the Clovis deposits (n=119) include side and end scrapers, blades, and utilized flakes (n=67), hammerstones (n=5) and biface preforms and biface fragments (n=33). Associated with these artifacts were clusters of debitage, presumably deposited as the byproducts
of the lithic manufacture process. Artifacts were not encountered below the Clovis deposits in this block.

**Results of 2004 Field Season**

Tables A15-12-13 present the distribution of artifacts recovered from the 2004 Field season at the Topper Site (38AL23). Excavations were carried out in two areas on the Terrace in 2004; the 5m x 9m block and a 4m x 8m block excavation along the N288-N290 gridlines. In all, a combined 384 artifacts were mapped on the alluvial Terrace over the course of the field season. Of these, 27 pre Clovis items were recovered from the lower three levels (15cm) of the primary 5m x 9m block in the Pleistocene Sands deposits. Below these deposits, 90 items from were mapped from the Pleistocene Terrace deposits. This excavation began at the top of the terrace at 97.35m. Three full (N242 E140 SE, N242 E140 SW, N242 E142 SW) and one partial (N242 E140 NE) 1x1 meter units were placed around the margins of BHT17 and within the grid system. Within these units, a cluster of lithic artifacts was mapped, the majority of items occurring between 96.90-96.80m. These artifacts were preliminarily identified as flakes (n=20), worked chert cobbles (n=1), bend breaks (n=11), flake tools (n=3), cores (n=2), and weathered chert cobbles (n=45) (Goodyear 2005:6). However, most (61) items recovered from the pre Clovis deposits from the Pleistocene Terrace in 2004 derive from unit N242 E140 and include two flake tools and three bend breaks.

A total of 236 artifacts were recovered from the Holocene and Paleoindian deposits from the N288-N290 4m x 8m block. Very few Woodland (n=3) and Archaic (n=19) artifacts were recovered from this block as evidenced by the profile map in Figure A23-15. Similar to the discoveries in this area in 2002, a dense Clovis floor was uncovered which is approximately 20cm in thickness and “overlain by relatively sterile” Holocene deposits (Goodyear 2005:7).
This “floor” contains 131 artifacts from the Clovis deposits, the majority consisting of blades (n=23), cores (n=27), and flakes (n=35) (Table A15-13). A total of five Clovis preforms were recovered from this block in 2004 in addition to nine additional bifaces from the Paleoindian levels.

2005-2012 Field Seasons

2005-2009 Southern Pleistocene Sands and Terrace Pleistocene Terrace Excavations

Since 2005, excavations into the Pleistocene age sediments at Topper have continued in four specific locations. These areas include excavations at the southern end of the Terrace surrounding BHT 17 from 2005-2009; excavations of Holocene and Pleistocene sediments to the north of BHT17 from 2009-2012; excavations of the Pleistocene Sands in three 1x1m quads along the eastern margin of BHT17 in 2005 and 2011; and the excavation of Holocene and Pleistocene sediments from a 4x4m block 20m north of the primary pre Clovis excavation from 2010-2012. Tables A15–14 through A15–18 present the distribution of mapped items by type for each provenience for each of the excavation areas. All levels excavated over the course of this time period derive from pre Clovis contexts with the exception of the 2009-2012 Northern Terrace excavation which includes materials from Holocene, Pleistocene Clovis, and Pleistocene pre Clovis deposits.

Between 2005 and 2009 excavations in 6 1m x1m units from the Pleistocene Terrace have resulted in the recovery of 428 artifacts preliminarily classified as flake tools, bend breaks, cores, or hammerstones based on initial observation (Table A15-14). The majority of these artifacts are bend breaks (n=172) or flake tools (n=177). In addition, total of 25 artifacts and 185 lithic specimens were preliminarily classified from the partial units in 2005 (Table A15-15). By the completion of the 2007 field season, excavation in units N242 E140 and N242 E142 had been taken to a depth of 95.25m, arbitrarily considered the base of the Pleistocene terrace excavation. One new quad, N244 E138 SE was opened in 2007 and taken to a depth of 96.55m by the completion of the field season. A total of 71 of the 314 lithic items mapped in 2007 derive from the N244 E138 quad (Table A15-16). The majority of items encountered in this unit were
classified as cortical chert pebbles. In 2008 excavation began in the Pleistocene Terrace of unit N242 E138 SE and continued through the completion of the 2009 field season. Of the 2,633 pre-Clovis items mapped from the Southern Pleistocene Terrace units between 2004 and 2009, approximately 16.6% were classified as tools whereas the remaining items consist of flakes, flake fragments debris and cortical chert and quartz pebbles.

2005-2012 Northern Pleistocene Sands and Terrace Pleistocene Terrace Excavations

Beginning in 2009 excavations commenced at Topper on in units N246 E136-E142 and N248 E136-E142. This area is referred to as the Northern Terrace block. During the 2005 field season, excavation of the Northern Terrace block consisted of the systematic removal of the Holocene Sands to the top of the Pleistocene Terrace at 97.15m. A total of 62 bifaces and biface fragments were recovered from these excavations in addition to smaller quantities of flake, core, and production tools. Between 2009 and 2012 excavations continued into the Pleistocene Terrace in 9 1m x1m quads to a depth of 96.65m. The results of this excavation are presented in Table A15-19. Of the 1,921 artifacts identified from these units, 81 artifacts were classified as bend breaks, the majority recovered from the Lower Pleistocene Sands and Upper Pleistocene Terrace. Excavation was not taken below 96.65m in this area.

Mapped Artifacts from 1998 Excavations at the Topper Site (38 AL23)

Appendix 15 below presents the mapped artifacts for each field season (1998-2012) of excavation on the Alluvial terrace at the Topper Site. Columns, in order from left to right include: provenience northing, provenience easting, artifact depth, Artifact classification, Artifact number, unit northing, unit easting. All artifact information was taken directly from the site level records on file at the South Carolina Institute of Archaeology and Anthropology (SCIAA).
