To the Graduate Council:

I am submitting herewith a thesis written by Bilin Chen entitled "Fatigue Study of Pipeline Steels." I have examined the final electronic copy of this thesis for form and content and recommend that it be accepted in partial fulfillment of the requirements for the degree of Master of Science, with a major in Materials Science and Engineering.

Peter K. Liaw, Major Professor

We have read this thesis and recommend its acceptance:

Carl J. McHargue, Yanfei Gao

Accepted for the Council:

Dixie L. Thompson

Vice Provost and Dean of the Graduate School

(Original signatures are on file with official student records.)
Fatigue Study of Pipeline Steels

A Thesis Presented for the
Master of Science
Degree
The University of Tennessee, Knoxville

Bilin Chen
August 2013
Acknowledgements

First of all, I would like to express my sincere thanks to my major advisor, Prof. Peter K. Liaw, for providing me with such a nice environment in which to learn, to do research and to grow. I really appreciate all the advice and encouragement over the past years.

I am also very grateful to the committee members: Prof. Carl J. McHargue and Prof. Yanfei Gao, for their kind help and guidance during my study.

My genuine thanks also go to Dr. Ke An from the Oak Ridge National Laboratory (ORNL) for the help on neutron experiments and data analysis, Dr. Andy Slifka and Ms. Elizabeth Drexler from the National Institute of Standards and Technology (NIST) for preparing the hydrogen-charged samples, and Mr. Guangfeng Zhao from The University of Kentucky for help on nanoindentation tests. Moreover, I would like to thank Dr. David Clarke from The University of Tennessee (UT), Mr. Doug Stalheim from DGS Metallurgical Solutions, Inc., Dr. Wei Zhang from Ohio State University (OSU), Dr. Govindarajan Muralidharan from ORNL, Mr. Louis Hayden from Louis E. Hayden Associates, and Mr. James Merritt from the US Department of Transportation, for great discussions and advices. Also, I would like to thank Mr. Douglas E. Fielden, Mr. Larry D. Smith, and Mr. Dan Hackworth from UT, for their great help in machining test samples. In addition, I appreciate Ms. Carol Hatmaker, and Ms. Tammy Enix from UT, for their work in the management of the project.

I appreciate Dr. Jieshan Hou from the Institute of Metal Research in the Chinese Academy of Sciences, and Dr. Gong Li from Yanshan University, China, for useful
discussions. I would also like to thank Dr. John Dunlap, Mr. Greg Jones, Mr. Maneel Bharadwaj, Mr. Joshua Burgess and Mr. John Bohling, from UT for technical support.

I am glad to be in a group where my colleagues all work hard to create a great environment so that we can all learn from each other and grow together. Many thanks are given to Dr. Gongyao Wang, Dr. Lu Huang, Mr. Wei Wu, Mr. Andrew Chuang, Mr. Lou J. Santodonato, Mr. Qingming Feng, Mr. Zhi An, Mr. Xie Xie, Mr. Wei Guo, Mr. Haoling Jia, Mr. Zhiqian Sun, Mr. Michael Hemphill, Mr. Zhi Tang, Mr. Gian Song, and Ms. Haoyan Diao at UT.

The project was supported by the US Department of Transportation, Pipeline and Hazardous Materials Safety Administration (PHMSA), under contract DTPH56-10-000001, with Mr. James Merritt as the Program Manager.

Lastly, I would like to dedicate my thesis to my parents, Zengyi Chen and Xuefei Yi, and my brother, Bihai Chen, who have always encouraged and supported me with their love.
Abstract

Two types of pipeline steels, Alloy B [Fe-0.05C-1.52Mn-0.12Si-0.092Nb, weight percent (wt.%)], and Alloy C [Fe-0.04C-1.61Mn-0.14Si-0.096Nb, wt.%], were tested. Vickers hardness and nanoindentation tests were used to obtain the hardness and elastic modulus. Compact-tension (CT) specimens were employed for fatigue experiments. Different frequencies (10 Hz, 1 Hz, and 0.1 Hz) and different stress ratios [0.1 and 0.5, stress ratio (R) is the ratio between $P_{\text{min}}$ [minimum applied load] and $P_{\text{max}}$ [maximum applied load]. $R = P_{\text{min}}/P_{\text{max}}$] were used, and the tests were done in air, at room temperature. The effects of frequencies and different R ratios on crack-growth rates were compared. It is concluded that a higher R ratio leads to a greater fatigue-crack-growth rate (FCGR), while frequency does not have much influence. Moreover, Alloy B tends to have a better fatigue resistance than Alloy C under various test conditions. The microstructures of two alloys were investigated by optical microscopy (OM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). Fracture surfaces show transgranular patterns, and fatigue striation was observed under the scanning electron microscope (SEM).

Another type of pipeline steel, X70 [Fe-0.053C-1.52Mn-0.25Cr-0.19Si-0.089Nb, weight percent (wt.%)], was also studied. Fatigue tests were performed at different load levels, and comparisons were made between different parts of weld and base metals. Fracture surfaces were observed by SEM to identify fatigue and fracture mechanisms.
Neutron-scattering-diffraction experiments were performed to study the deformation behavior around the crack tip of X52 [Fe-0.071C-1.06Mn-0.24Si-0.026Nb, weight percent (wt.%)] and X70 pipeline steel. Both the hydrogen-charged sample and as-received sample were used to detect the influence of hydrogen. Preliminary results are presented in this thesis.

Chapter 1 Introduction

Due to increasing environmental and monetary costs of using traditional fossil energy, the development of alternative energy sources is becoming more and more significant. Among them, solar and wind energies are the most promising ones to contribute to sustainable energy requirements. However, the productivity of solar and wind energies is highly dependent on natural solar and wind cycles, which are not necessarily consistent with highs and lows of energy demands. Finding ways to store energy is a critical component in solving this problem. It has been proposed that solar and wind energies can easily be used to separate water, thus generating hydrogen, which can be used as the energy-storage medium. Also, with the increased development of the hydrogen fuel-cell technology for the automobile industry, the demand for hydrogen is expected to increase. Therefore, how to transport hydrogen to end users quickly and efficiently becomes an issue [1-5].

It is well known that the most economic and efficient way to transport a large amount of hydrogen is through steel pipelines, but the mechanical behavior of these pipeline steels will be deteriorated by exposure to the hydrogen environment [6-8].

Currently, pipelines are made of steels, which often become embrittled by hydrogen, causing the reduction of ductility, strength, and fatigue life. We call them hydrogen embrittlement (HE), and hydrogen-assisted fatigue-crack-growth (HAFCG) behavior. In this thesis, we will focus on the fatigue-crack-growth characteristics [1].
Chapter 2 Literature Review

2.1 Development of Pipelines

The origin of the development of pipelines goes back to 3000 BC when Egyptians used copper pipes to transport water [1]. The modern pipeline industry developed from the oil business boom which began in the 19th century. Since the turn of the 20th century the pipeline industry has been growing tremendously. It is estimated that the total length of high pressure transmission pipelines was about 3,500,000 km by 2007, over 60 percent of which carry natural gas, while the rest carry crude oil and other petroleum products [9].

2.2 Types of Pipelines

Pipelines can be used to transport gas, oil, water, etc. They can be classified into three groups depending on the purpose [10]:

1. Gathering pipelines are used to bring crude oil or natural gas from wells to a treatment plant or facility.
2. Transportation pipelines are mainly long pipes with large diameters, and they are used to move oil, gas, and other refined products between cities, countries, and even continents.
3. Distribution pipelines are used to transport the products to the final consumer. For example, gas is distributed by them to homes and businesses branches.

In this thesis, we focus on transportation pipelines that are used to transport hydrogen [11]. There are pipelines made of metals, plastics, or composites. Due to economic and environmental issues, the majority of transportation pipelines for hydrogen are steel pipelines.
2.3 Effects of Hydrogen on Mechanical Behavior of Pipeline Steels

The change in the mechanical behavior of pipeline steels is due to the response of material to hydrogen [8]. Also, the degradation mechanism is highly influenced by the way of exposure, or the type of attack, and sometimes opposite effects might occur [12]. Generally speaking, the elastic properties will not be affected much with the presence of hydrogen. On the other hand, the ductility, fracture toughness and fatigue-crack-growth behavior will be harmed in the atmosphere of hydrogen [8].

2.3.1 Effects on Tensile Properties

In the literature, typical tensile properties were referred to yield stress, ultimate tensile strength (UTS), the elongation of the material, and reduction in area.

Hofmann and Rauls in Ref. [14] conducted the earliest tensile test in hydrogen gas up to 15.2 MPa [megapascal]. A 0.22% carbon steel was used in the study. Their results were plotted in Figure 1. It can be seen from the figure that the elongation stayed around 30% with the increase of hydrogen pressure, while the reduction of area showed a trend to decrease with the increase of hydrogen pressure. The reduction of area was around 30% in 15.2 MPa hydrogen, compared to 64% when tested in air.

Similar tests were also done for Armco iron (0.028 %C), 0.22 %C (normalized), and 0.45% C (unalloyed, normalized) carbon steels in hydrogen (0.10 MPa ~ 15.2 MPa) [16], and the reduction in area results were consistent with Hofmann and Rauls’ tests. Reduction in area decreases with the increase of hydrogen pressure. However, the elongation at failure did not stay the same, as it also decreases with the increase of hydrogen pressure.
Another test was performed by Hofmann and Rauls [15], in which cold-drawn 0.22% carbon steel was used. What is shown in Figure 2, is that the UTS decreased with the increase of hydrogen pressure. Actually, the tensile strength decreased more than 40%, as the hydrogen pressure increased from 0.10 MPa to 10.1 MPa.

Cialone and Holbrook [36] conducted a study trying to determine the influence of hydrogen on ductility loss in cast carbon steels. They found that in the as-cast clean (low metalloid content) steel, the effect was obvious and hydrogen promoted fracture by cleavage. However, for annealed samples, not only did the ductility increase but also the resistance to ductility losses increased in hydrogen environment.

In Hofmann and Rauls’ study [16], the UTS of Armco iron (0.028 %C), 0.22 %C (normalized), and 0.45 %C (unalloyed, normalized) carbon steels in hydrogen and air were compared, as we can see in Table 1. Basically the UTS did not change because of the presence of hydrogen. Some tensile properties tests were conducted, and the information is listed in Table 2 [13]. In this study, four different materials, ASTM A-515 Gr 70, AISI 1042 normalized, AISI 1042, and Armco iron, were investigated. It is shown in this table that the yield stress and the UTS did not change because of the environment, which is consistent with the findings by Hofmann and Rauls [16]. It was noted that the elongation and reduction in area decreased when they were tested in hydrogen, as expected.

Some other studies showed the difference in yield strength. In Ellis et al.’s study [17], in order to increase the yield strength of Alloy P1 (0.092 wt.% Carbon) and Alloy P2 (0.094 wt.% Carbon), the steel blanks were pretrained up to 15%. Then the samples were
cathodically-charged with hydrogen. A thin layer of copper was used to cover the surface of the sample to prevent hydrogen leaking. After the hydrogen-charging process, the sample was held at room temperature for 24 hours to let hydrogen distribute uniformly in the whole sample. Figure 3 showed that the yield strength decreased for the hydrogen-charged samples, at different strain levels.

However, some tests have shown different results. In Pussegoda and Tyson’s study [18], the results actually indicated that the yield strength increased when the samples were charged with hydrogen. In their study, two sets of experiments were performed. (1) The specimen was quenched and tempered (QT specimen). The QT specimens were charged in hydrogen gas until the concentration was around 1 ppm (wt.%). (2) Another specimen was directly quenched (DQ specimen). The DQ specimens were cathodically-charged to a hydrogen concentration to a range of 1 to 5 ppm. Both samples were stored in nitrogen before testing. The tests were conducted from temperature of -196°C to 135°C. To prevent the loss of the hydrogen gas, these samples were electroplated with a thin layer of cadmium. As shown in Figure 4, on both conditions, the yield stress for the charged sample is higher than the uncharged one in most of the temperature ranges, except at higher temperatures where they seem to converge.

2.3.2 Effects on Fatigue-Crack-Growth Behavior

Though hydrogen embrittlement (HE) has been researched for many years, the mechanism is not fully understood. Nor is the mechanism for fatigue-crack-growth completely understood. Therefore, the mechanism for fatigue-crack-growth under the influence of hydrogen is complicated [1].
2.3.2.1 Three Regions of Fatigue-Crack-Growth

As presented in Figure 5, the crack-growth behavior of materials is generally divided into three regions [19, 20]. Stress intensity factor range (△K) is defined as follows,

\[ \Delta K = K_{\text{max}} - K_{\text{min}} \]

Where \( K_{\text{max}} \) is the maximum stress intensity factor per cycle, \( K_{\text{min}} \) is the minimum stress intensity factor per cycle. In region 1, \( \Delta K \) is very low, and the crack propagates slowly. When \( \Delta K \) continues to increase and goes over a threshold value (\( \Delta K_{\text{th}} \)), it will be in region 2 where the crack-growth rate increases significantly. A typical relationship can be drawn between the fatigue-crack-growth rate (FCGR) and \( \Delta K \) in this region, which is referred to as the Paris Law [21]:

\[ \frac{da}{dN} = A(\Delta K)^m \]

where \( \frac{da}{dN} \) is the change in crack length per cycle, A and m are material constants. As \( \Delta K \) continues to increase to high levels (there is a critical value \( K_{\text{IC}} \)), the Paris Law will no longer be applied, and the FCGR becomes rapid and unstable, which is region 3.

2.3.2.2 Three Types of Hydrogen Assisted Fatigue-Crack-Growth (HAFCG)

As presented in Figure 5, there are three types of possible effects of hydrogen on the fatigue-crack-growth of materials [1, 19, 20]. \( K_{\text{IH}} \) (the monotonic crack-growth threshold in hydrogen) is defined as the stress intensity beyond which the subcritical crack propagation happens in the material exposed to hydrogen when a static load is applied. In their studies [1, 19, 20], it was assumed that \( K_{\text{IH}} \) values in the dynamic-loading
conditions can represent those in static-loading conditions, and the static $K_{IH}$ values can reflect the hydrogen embrittlement (HE) property.

In type A, $K_{IH} = K_{IC}$, the material will not be affected by HE under the static-loading condition. However, when it is tested in the dynamic-loading condition, such as cyclic loading, the fatigue-crack-growth rates will be higher than those in the inert or air environment, and the $\Delta K$ needed for the initiation of crack-growth is also lower. For type B, $K_{IH} < K_{\text{max}} < K_{IC}$, the material suffers from static HE, but dynamic loading will not make any difference when $K_{\text{max}} < K_{IH}$. The fatigue-crack-growth is not influenced by hydrogen in that region. In a real on-site situation, many materials will be affected by hydrogen in both regions. Thus, we see combined influences as in Type C in Figure 5.

### 2.3.2.3 Two Common Mechanism for the HE of Steel under Monotonic Loading

The mechanism of HE is not fully understood, and there is no agreement on the mechanisms for HE of steels under monotonic loading [22-25]. There are two common mechanisms that have been proposed. One mechanism contends that the failure in hydrogen is due to “hydrogen-enhanced decohesion” (HEDE) [27-29]; the other proposes that it is because of “hydrogen-enhanced local plasticity” (HELP) [30-34].

Both mechanisms are based on the assumption that the gas hydrogen will form atomic hydrogen and then diffuses to the stress region. The HEDE mechanism holds the opinion that the cohesive strength in the hydrogen-enriched region will be reduced, which will deteriorate the mechanical property of the materials. On the other hand, HELP proposed that hydrogen will increase the mobility of the dislocation, resulting in a localized plastic instability, which will promote the deformation behavior. Some literature results showed
that the dislocation mobility was indeed improved by hydrogen by the in-situ transmission electron microscopy (TEM) [22], but the results on this issue are mixed [22, 23, 30].

2.3.2.4 HAFCG Studies

Cialone and Holbrook conducted a comprehensive study on the tests of pipeline steels in hydrogen environment [35]. Figure 6 shows their test results on the comparison of fatigue test in 6.9 MPa hydrogen and nitrogen. A load stress ratio \[\text{stress ratio } (R) = \frac{P_{\text{min}}}{P_{\text{max}}}, \text{where } P_{\text{min}} \text{ is the minimum applied load and } P_{\text{max}} \text{ is the maximum applied load.} \] of 0.1 was used for this study. It can be seen from the figure that the FCGR of X42 was higher than that of X70 at the same \(\Delta K\) level. Moreover, it is clear that when the tests were run in hydrogen atmosphere, the propagation rates increased tremendously. Actually, the FCGR can be 150 times faster in hydrogen than in nitrogen for X42. It can also be seen from the figure that the difference of fatigue-crack-growth (FCGR) rates decreased at lower \(\Delta K\) levels.

Cotrill and King also performed tests on a kind of C-Mn steel in hydrogen and air [35]. A stress ratio of 0.1 and a frequency of 0.1 Hz were used in the tests. They found that the difference of FCGRs between specimens tested in two environments was not much when \(\Delta K\) level was low (\(\approx 22 \text{ MPa m}^{0.5}\)). However, at a higher \(\Delta K\) level (\(\approx 40 \text{ MPa m}^{0.5}\)), the FCGRs in hydrogen were nearly 20 times of those in air.

There are a few testing variables that need to be taken into consideration when we are trying to study the FCGR of pipeline steels in hydrogen. These variables, including hydrogen pressure, test stress ratio, test frequency, strength and alloy microstructure, may
affect the FCGRs of materials when they are tested in hydrogen, in various ways [1]. They are to be reviewed in the subsequent sections.

2.3.2.5 Effects of Hydrogen Pressure on HAFCG

Figure 7 presents the test results reported by Zawierucha and Xu [38]. Fatigue-crack-growth tests were performed with stress ratio of 0.1 under various hydrogen pressures. The FCG as a function of hydrogen pressure when $\Delta K = 22$ MPa $m^{0.5}$ has been plotted as Figure 7. It can be concluded that after the initial large change of FCG when the hydrogen pressure was 1.4 MPa. The FCG only increased 1.5 times as the hydrogen pressure changed from 1.4 MPa to 20.7 MPa.

The effects of hydrogen pressure was also investigated by Holbrook for X42 steel when $\Delta K = 22$ MPa $m^{0.5}$, at a stress ratio of 0.25 and frequency of 0.1 Hz [39]. They found that the ratio of FCGR in hydrogen to that in nitrogen increased as a power function of the hydrogen partial pressure for pressures from 0 to 6.9 MPa. Nanninga. et al. thought that the lower dependence of hydrogen pressure might be caused by the nonequilibrium concentration of hydrogen under cyclic loading. The higher dependence of hydrogen pressure might be obtained by using lower-frequency tests since the concentration of hydrogen in the material might be closer to the equilibrium condition [1].

Walter and Chandler also evaluated this with pressures ranging from 6.9 MPa to almost 100 MPa, on SA-105 Grade II steel [39]. They found that FCGR increased tremendously with the pressure. But, there was little difference after the pressure went above 69 MPa, all the way up to 100 MPa.
2.3.2.6 Effect of Stress Ratio on FCG Behavior

Since the cyclic stress intensity range $\Delta K$ is related to the stress ratio by

$$\Delta K = (1 - R) K_{max}$$

So the maximum stress ($K_{max}$) will be higher as $R$ increases, at a given $\Delta K$ [1].

Cialone and Holbrook investigated the influence of hydrogen on the fatigue behavior of an X42 pipeline steel [37]. By comparing experiment results in hydrogen and nitrogen environments, they found the influence of stress ratios on crack-growth rates in hydrogen and nitrogen at a constant $\Delta K$ value. As we can see from Figure 2, in nitrogen environment, the crack-growth rate increases as $R$ increases; while in a hydrogen environment, the growth rate stays the same when $R$ is below 0.5, and increases when $R$ is above 0.5. Generally X42 has a higher crack-growth rate in hydrogen than in nitrogen, but the difference decreases with increasing $R$ when $R < 0.5$, and increases again beyond the $R$ value of 0.5.

2.3.2.7 Effects of Frequency on HAFCG Behavior

In Cialone and Holbrook’s study on X42 pipeline steel [37], they found that there was little difference when the test was conducted in hydrogen at 1 Hz and 0.1 Hz, while the crack-growth at 10 Hz was slower.

The effect of frequency was also studied by Walter and Chandler for an ASME SA-105 Grade II steel (0.23% C and 0.62% Mn) with a stress ratio of 0.1 [40]. As can be seen in Figure 9, compared with tests done in He, the FCGRs in hydrogen were much higher than that in He. Also, FCGR increased as the test frequency decreased. Note that the highest
frequency here is 1 Hz and the lowest is 0.00083 Hz. With the development of the test technique, there is no doubt that a data base with a wide range of frequencies will be established.

2.3.2.8 Effects of Yield Strength and Microstructure on HAFCG Behavior

Investigations for the microstructure effects on HAFCG behavior have been conducted by Cialone and Holbrook on C-Mn steels [41-44]. The FCGR results showed that the fully-ferritic alloy seems to be more sensitive to hydrogen than the pearlite alloy, and the fractographic figures also suggested that hydrogen has a stronger influence on ferrites than pearlites. For the fully-ferritic alloy, when it was tested in hydrogen, fatigue-crack-growth happened mostly along the grain boundaries, while it was almost 100% transgranular in nitrogen. In Carroll and King’s study on C-Mn pipeline steels [45], no large difference was found in FCGRs for specimens with different microstructures and strengths. It should be noted that in Cialone and Holbrook’s study [42-44], X70 showed the lowest FCGRs in hydrogen, which is contrary to the results from statically-loading tests in hydrogen, where higher strength alloys are more susceptible to HE. More studies need to be done on various pipeline steels on this issue. Present literature resources did not provide a correlation among the microstructure, strength, and HAFCG behavior.

2.3.2.9 Other Variables

Crack closure or shielding may influence the FCG behavior of steels in hydrogen [45, 46]. Tensile overload will cause fatigue retardation in crack propagation because of the crack tip plasticity [48-50]. But Walter and Chandler [40] observed that the overload to $1.5 K_{\text{max}}$ did not affect the FCGR in 103.4 MPa hydrogen for an ASME SA-105 Grade II
steel, while retardation in FCG occurred after overload when specimens were tested in 34.5 MPa helium. It seems that HE influenced the plasticity effect in this case [8].

Effects of gases that might inhibit the HAFCG were also studied by some researchers [8, 39, 51]. Certain gases, such as C₂H₄ and O₂, might be able to inhibit the hydrogen effect greatly by forming semi-stable bonds with iron on the surface. Other gases, such as CH₄, H₂S, natural gas, might either increase the FCGR or have no effect. Inhibitor-gas studies might be promising, but they need to deal with the safety issues since some of the gases can be inflammable, and these impurities might have a detrimental effect on the performance of the hydrogen fuel cell. Filtering processes need to be considered when high purity hydrogen is required for application.

2.4 Summary

In summary, hydrogen will serve as one of the alternative energies. The most economic and practical way to transport a large quantity of hydrogen is through steel pipelines. The exposure to hydrogen will deteriorate mechanical properties of pipeline steels. HE has been extensively studied for several decades, but the mechanism is still not clear. Two common mechanisms, “hydrogen-enhanced decohesion” (HEDE) [27-29] and “hydrogen-enhanced local plasticity” (HELP) [30-34], were briefly reviewed. The mechanisms of hydrogen-assisted fatigue-crack-growth (HAFCG) are lacking, since both the mechanisms for HE and FCG are not clear, and dynamic loading is different from static loading in terms of hydrogen effects. Some variables; stress ratio, test frequency, gas pressure, microstructure, strength, etc. that might influence the HAFCG of steels have been briefly reviewed. The role of crack closure should also be considered for the HAFCG behavior, which might be different because of the presence of hydrogen. Overall,
many study results have proved that the FCGR increased significantly in the hydrogen environment, compared with nitrogen or air atmosphere. A better understanding of this behavior is needed for the pipeline industry and more experiment data for pipeline steels are required concerning different variables and test parameters. Ways to inhibit HAFCG should be proposed and used in future pipeline-transportation systems.
Chapter 3 Fatigue-Crack Propagation Behavior of Pipeline Steels (Alloy B and Alloy C)

3.1 Introduction

In the process of hydrogen transportation, the change of external loads, combined with the pressure variation, will create a fatigue process for pipeline steels, which will definitely contribute to the final failure of the steels. Thus, the fatigue property of the material needs to be improved since once the early cracks are formed, the FCGR would be accelerated because of the hydrogen environment [52-54].

Since we do not have a general rule that can be applied to the fatigue-crack-growth behavior of pipeline steels exposed to hydrogen, data is needed concerning the hydrogen-influenced fatigue-crack behavior of pipeline steels. In order to study the influence of hydrogen, the reference experiments should be conducted in air atmosphere.

As the pivotal aspect of present work, fatigue-property evaluation is very important. As shown in Figure 5, the fatigue behavior of materials is divided into three stages: stage I (crack initiation), stage II (crack propagation) and stage III (final fracture). These three stages are of vital significance in the determination of materials’ fatigue life. When a structural component is subjected to cyclic loading, in order to assess the structural reliability, or even predict the crack-growth life, the information on fatigue-crack-growth rates is irreplaceable [55, 56].
3.2 Materials and Experiment Details

3.2.1 Materials

We have two kinds of alloys to study, Alloy B and Alloy C. They were thermo mechanical control processed (TMCP) in a hot-rolling mill, and in a coil/plate form prior to the pipe-making process. Their chemical compositions are shown in Table 1. As we see, Alloy C has less carbon (0.04 wt.%) than Alloy B (0.05 wt.%). Also, the content of Mn and Cr in Alloy C (1.61 wt.%, and 0.42 wt.%) is higher than those in Alloy B (1.52 wt.%, and 0.25 wt.%).

3.2.2 Microstructure Characterization

The characterization of the microstructures was documented [6]. We used the same materials as the Alloy B and Alloy C in this paper.

According to the results by Stalheim and his team [6], Alloy B consisted of about 90% coarse polygonal ferrites and 10% coarse acicular ferrites (a type of low carbon bainites), by volume fraction. The microstructures of Alloy C and Alloy B were very similar except that there is a small portion of upper bainite (~2%), 8% coarse acicular ferrite (a type of low carbon bainite), and 90% polygonal ferrites. The upper bainites appear dark in the lighted microscope. This is caused by the lathe ferrite with limited carbon precipitation between the laths since there is only 0.04% of carbon in Alloy C. The optical microscopy (OM), scanning electron microscopy (SEM) and transmission electron microscopy (TEM) analysis is shown in Figures 10 to 13.
3.2.3 Vickers-Hardness Tests

Samples were cut, mounted, and mirror polished to make sure that the surface was flat. Vickers-hardness experiments were performed on the sample at 11 different locations under a load of 500 gf [gram force], with a testing time of 15s. Data was then averaged to obtain the Vickers hardness value of the sample.

3.2.4 Nanoindentation Tests

Samples were prepared for nanoindentation tests to obtain the elastic modulus and mechanical behavior near the surface area. Data can also be used to compare to bulk properties. A Hysitron TriboScope (Minneapolis, MN) mounted on a Quesant atomic force microscope (AFM) (Agoura Hills, CA) was employed in this study. A cube-corner diamond indenter was used. Loading (10s), holding (10s) and unloading (10s) (altogether 30s) were chosen. Different loads were used to see the reaction of material and to compare the hardness values. For each test condition, 5 to 6 indents were made to minimize error.

3.2.5 Fatigue-Crack Propagation Tests

The Compact-tension (CT) specimen was employed in our study. The specimen was prepared, according to the American Society for Testing and Materials (ASTM) Standards E 647-99. It has a notch length of 10.16 mm, a width of 50.8 mm, and a thickness of 6.35 mm. The geometry of the sample is shown in Figure 14. A computer-controlled Material Test System (MTS) servohydraulic machine was used to perform the fatigue-crack-growth experiments. The CT specimens needed to be pre-cracked first. Right after the pre-crack, the crack-growth experiments were performed, until the failure of the specimen. All specimens were tested under a constant-range-control mode with
frequencies of 10, 1, and 0.1 Hz, load ratios, R of 0.1 and 0.5 \( R = P_{\text{min}}/P_{\text{max}}, P_{\text{min}} \) and \( P_{\text{max}} \) are the applied minimum and maximum loads, respectively]. The fatigue test matrix is shown as Table 4. The crack length was measured by a crack-opening-displacement (COD) gauge through the compliance method [57]. The stress-intensity factor, K, is obtained by the following equation:

\[
K = \frac{P(2 + \alpha)}{B \sqrt{W} (1 - \alpha)^{3/2}} \left( 0.886 + 4.64\alpha - 13.32\alpha^2 + 14.72\alpha^3 - 5.6\alpha^4 \right)
\]

where \( a \) is the crack length, \( W \) is the specimen width, \( \alpha = a/W \), \( B \) is the specimen thickness, and \( P \) is the applied load, the stress-intensity-factor range, \( \Delta K \) is defined by

\[
\Delta K = K_{\text{max}} - K_{\text{min}}.
\]

where \( K_{\text{max}} \) and \( K_{\text{min}} \) are the maximum and minimum stress-intensity factors, respectively. The crack-growth rates (da/dN) and \( \Delta K \) data were generated by the MTS machine automatically.

### 3.3 Results and Discussion

#### 3.3.1 Vickers-Hardness Results

The results of Vickers Hardness tests are shown in Table 5. From the tests, the Vickers Hardness of Alloy C is around 230 HV [Vickers Pyramid Number], while that of Alloy B is about 201 HV. The difference of hardness is probably due to the larger amounts of Mn and Cr in Alloy C which would increase the hardenability of alloy steels [58].
3.3.2 Nanoindentation Results

For the data analysis, we chose 4 sets of data from each load level, and calculated the average value of the elastic modulus and hardness. From the results, we found that the elastic modulus and hardness tend to drop with increasing load. Also, the value of hardness for Alloy C is greater than Alloy B for all the load levels, while the elastic moduli were around the same level.

To give a better comparison between these two alloys, we averaged the data from all the five load levels [2, 4, 5, 7, 8 mN (millinewton)], and we found that the elastic modulus of Alloy B and Alloy C are basically the same, 183.2 GPa [gigapascal] (Alloy B) and 185.7 GPa (Alloy C), respectively. The average value of hardness for Alloy B is 4.7 GPa, while that of Alloy C is 5.8 GPa. The ratio of nano hardness (B to C) is 0.81 which is similar to that for Vickers hardness, 0.87. The properties in these two scales of hardness values seem consistent.

3.3.3 Fatigue-Crack-Propagation Tests

The fatigue-crack-growth-rate experiments were finished on two kinds of base pipeline steels [Alloy B (Fe-0.05C-1.52Mn-0.12Si-0.092Nb, weight percent (wt.%)) and Alloy C (Fe-0.04C-1.61Mn-0.14Si-0.096Nb, wt.%)] at different frequencies (10 Hz, 1 Hz, and 0.1 Hz) and different R ratios (0.1 and 0.5). The crack-growth rates (da/dN) as a function of ΔK are shown in Figures 15 to 22. During constant amplitude crack-growth experiment, the crack-propagation rates increase with increasing ΔK.

Figures 15(a) and (b) plot the fatigue-crack-growth results of Alloy B at different frequencies, and at R ratios of 0.1 and 0.5 respectively. Figures 16(a) and (b) show the
results of Alloy C. According to the figure, in air conditions, the frequencies didn’t influence the FCGRs significantly.

Figures 17(a)-19(a) plot the fatigue-crack-growth results of Alloy B at different R ratios of 0.1 and 0.5 and at frequencies of 10, 1, and 0.1 Hz. Figures 17(b)-19(b) showed the FCGRs results of Alloy C at different R ratios of 0.1 and 0.5 and at frequencies of 10, 1, and 0.1 Hz. In general, the FCGR at an R ratio of 0.5 is larger than at an R ratio of 0.1 for various frequencies. This trend is probably due to the fact that when R is larger, the mean stress will be greater for a certain maximum stress, as in this equation [59],

$$\sigma_m = \frac{1 + R}{2} \sigma_{max}$$

where $\sigma_m$ is the mean stress, and $\sigma_{max}$ is the maximum stress. The amplitude of mean stress plays an important role in affecting the fatigue behavior of materials. Higher mean stress leads to greater FCGRs. It can also be explained by the bigger maximum stress intensity caused by higher R. Since the cyclic stress-intensity-factor-range $\Delta K$ is related to the stress ratio by

$$\Delta K = (1 - R) K_{max}$$

So the maximum stress intensity ($K_{max}$) will be higher as R increases, at a given $\Delta K$ [1]. And since the crack-growth rates were higher when $R = 0.5$, the final fracture happened at a lower $\Delta K$ than when $R = 0.1$.

By comparing the effect of stress ratio for Alloys B and C, especially at the frequency of 1 Hz (as shown in Figure 18), we also found that the FCGR for Alloy B did not increase
as much as that for Alloy C. So it seems that Alloy B is not as sensitive to R ratio as Alloy C is.

Figures 20 to 22 plot the comparison of fatigue-crack-growth results of Alloy C and Alloy B at frequencies of 10, 1 and 0.1 Hz and R ratios of 0.1 and 0.5. The FCGRs of Alloy C is greater than those of Alloy B in various conditions. It can also be seen from the figures that the difference in FCGRs between these two alloys is greater when the tests were performed at the stress ratio of 0.5, which also suggests that the FCGR of Alloy C increased more than Alloy B with increasing stress ratio.

From the literature survey we know that difference in FCGRs between Alloy B and Alloy C might be due to the differences in microstructures [6]. From the microstructural characterization of Alloy B and Alloy C, in case of volume fraction, Alloy B was characterized by 90% coarse polygonal ferrites and 10% coarse acicular ferrites (a type of low carbon bainites), while Alloy C was characterized by a small portion of upper bainites (~ 2%), 8% coarse acicular ferrites (a type of low carbon Bainite), and 90% polygonal ferrites. So the microstructure was similar except for the small portion of upper bainites, as can be seen in Figures 12 and 13. The difference in fatigue resistance might be caused by this upper bainite influence. Further investigations are needed to explain this behavior.

**3.3.4 SEM Image of the Fracture Surface**

Figure 23 presents the SEM images of the side-view fracture surface of Alloy C. Figures 23(a), (b), and (c) represent the micrographs of the small $\Delta K$, middle $\Delta K$, and large $\Delta K$,
respectively. We can also clearly see the fracture surface becomes rougher with the increase of $\Delta K$. Also, secondary cracks were observed at large $\Delta K$.

Figure 24 presents the SEM image of the fracture surface of Alloy B and Alloy C, when $\Delta K = 10 \text{ MPa.m}^{0.5}$. Both of them show transgranular patterns.

Figure 25 presents the fracture surface of Alloy B at middle and high $\Delta K$. Ductile striations can be clearly seen at this higher magnification. It can also be seen that striation patterns seem more obvious at high $\Delta K$ level.

### 3.4 Conclusions

- In general, frequencies don’t significantly influence the FCGR behavior on the current pipeline steels (Alloys B and C).
- The two alloys exhibited different fatigue behavior in air. In general, Alloy B has slower crack-growth rates than Alloy C does, that is to say, Alloy B has a better fatigue resistance than Alloy C.
- From the fatigue-crack-growth results of Alloy B at various frequencies and different R ratios of 0.1 and 0.5, we find that FCGRs at an R ratio of 0.5 are larger than at an R ratio of 0.1.
- The scanning-electron-microscopy (SEM) images of the side-view fracture surface were taken at small, middle and large $\Delta K$ ranges, respectively. It is clear that the fracture surface becomes rougher with increasing $\Delta K$. Moreover, secondary cracks are observed at higher $\Delta K$.
- The fracture surfaces of both pipeline steels show transgranular patterns, and ductile striation patterns can be clearly seen at higher magnifications.
Chapter 4  Fatigue Study of X70 Pipeline Steel Welds

4.1 Introduction

Steel pipeline is the least expensive way to transport a large amount of hydrogen [6]. The most economic method to construct steel pipelines is through welding [60]. Due to the microstructure inhomogeneity and high residual stresses, the weld part in a steel pipeline is very susceptible to hydrogen embrittlement (HE). Compared to the base metal, the literature information on the study of the weld region is far from enough. Much input is needed to characterize the mechanical behavior of the weld region in the hydrogen atmosphere. Actually, during a Hydrogen Pipeline Workshop [61] in which members of academia, national laboratories, industrial gas and energy companies, engineering firms, and federal agencies participated recently, several top-priority research and development (R & D) needs for steel pipelines were pointed out. More than half of the top-priority research topics were related to the investigation of mechanical behaviors in the weld region, such as the heat-affected zone (HAZ). Moreover, some recent studies about pipeline steels suggested that the weld part has lower fatigue resistance and higher fatigue-crack propagation rate, when compared with its base metal [62]. Therefore, research on the mechanical behavior of the weld region of steel pipelines has become important and much data is needed for the improvement of welding techniques and better design of future pipelines.

X70 pipeline steel welds, a very common alloy design which has been used in the past years for gas and oil transmission pipeline infrastructure [6], will be studied. Results between weld and base metals will be compared.
4.2 Materials and Experiment Details

4.2.1 Materials

An X70 girth weld plate was employed in the study. The dimensions of the plate are approximately 520 mm (length), 270 mm (width) and 22 mm (thickness). The chemical compositions are shown in Table 6. The base metal has less carbon (0.053 wt.%) than the weld metal (0.141 wt.%). When tensile tests were run in air, the yield strength for the base metal was found to be 553 MPa, and the ultimate tensile strength was 640 MPa [63].

The CT specimen for the weld metal was machined according to Figure 26 so that the crack would grow in the weld and two samples were machined through the thickness direction. As shown in Figure 26, the weld is a V shape. The two samples through the thickness direction were characterized as weld (out), as the upper sample near the outside of the pipe, and weld (in), as the sample near the inside of the pipe.

4.2.2 Vickers-Hardness Tests

For the base metal, samples were cut, mounted, and polished to make sure the surface was flat. Vickers hardness tests were performed on the sample at 8 different locations, under a load of 500 gf, with a testing time of 15s. Data was then averaged to obtain the Vickers hardness value of the sample.

In order to compare the hardness of different regions of the X70 sample, we measure the Vickers Hardness along the direction normal to the fusion line, as shown in Figure 27(a). Moreover, we performed tests along the center line of the weld region to see the difference of hardness at different parts of the weld, as can be seen in Figure 28(a).
4.2.3 Fatigue-Crack-Propagation Tests

Compact-tension (CT) specimens were employed in our study. The specimen was prepared according to the American Society for Testing and Materials (ASTM) Standards E 647-99. It has a notch length of 10.16 mm, a width of 50.8 mm, and a thickness of 6.35 mm. The geometry of the sample is shown in Figure 14. A computer-controlled Material Test System (MTS) servohydraulic machine was used to perform the fatigue-crack-growth experiments. The CT specimens were first pre-cracked to a crack length of 3.84 mm. The crack growth experiments were performed after the pre-crack. Specimens were tested under different load levels, with the same frequency of 10 Hz, and R ratio of 0.1. The crack length was measured by a crack-opening-displacement (COD) gauge through the compliance method [57]. The stress-intensity factor, K, is obtained by the following equation:

\[
K = \frac{P(2 + \alpha)}{B\sqrt{W(1 - \alpha)^{3/2}}} \left(0.886 + 4.64\alpha - 13.32\alpha^2 + 14.72\alpha^3 - 5.6\alpha^4\right)
\]  

where \(a\) is the crack length, \(W\) is the specimen width, \(\alpha = a/W\), \(B\) is the specimen thickness and \(P\) is the applied load.

The stress-intensity-factor range, \(\Delta K\) is defined by

\[
\Delta K = K_{\text{max.}} - K_{\text{min.}} \quad (2)
\]

where \(K_{\text{max.}}\) and \(K_{\text{min.}}\) are the maximum and minimum stress-intensity factors, the crack growth rates (\(da/dN\)) and \(\Delta K\) were generated by the MTS machine automatically.
4.3 Results and Discussion

4.3.1 Vickers-Hardness Results

From the tests, the Vickers Hardness of X70 base metal is around 213 HV. For the comparison of the hardness of different regions of the X70 sample, the results are shown in Figure 27. The softest part was in the HAZ, which is as low as 180 HV, while the hardest part is in the upper part of the weld region, which goes to as high as 285 HV. In the bulk part of the base metal, the hardness stays around 210 HV. However, the data in the weld region scatters, so we measure the hardness along the center line of the weld to investigate the hardness variation.

In Figure 28, we see that the hardness varies with different parts of the weld. It can go to as high as 265 HV in the upper weld, and as low as 200 HV at the location around the center of the weld. So a micro-hardness map of the whole weld region is quite necessary in order to have full understanding of the mechanical behavior of the weld region.

4.3.2 Fatigue-Crack-Propagation Behavior

To date, the fatigue-crack-growth-rate experiments were finished on the X70 base metal under different maximum loads of 2.5, 3.5, 4.5, 5, 5.4, 6, and 7 kN, at a frequency of 10 Hz and R ratio of 0.1. The crack growth rates (da/dN) as a function of ΔK are shown in Figure 29. From this figure, we can see that the results from different load levels were normalized by ΔK and the crack growth rates (da/dN) as a function of ΔK curves are consistent among different load levels, which suggested that the stress intensity factor range (ΔK) is the critical factor that determined the FCGRs. Figure 30 plots the load level versus cycles to failure. It can be seen from this figure that the fatigue life decreases with
the increasing load level. While the cycles to failure was around $10^5$ when $P_{\text{max}} = 7 \text{ kN}$, it was more than $10^6$ when the $P_{\text{max}}$ was less than 3.5 kN.

Moreover, the fatigue behavior of base metal and weld metals were compared under the same condition ($P_{\text{max}} = 5 \text{ kN}, R = 0.1, f = 10 \text{ Hz}$). In particular, we also divided the weld group into upper part (close to the outside of the pipe) and lower part (close to the inside of the pipe). The comparison between base metal and upper part of the weld metal and the comparison between the base metal and the lower part of the weld metal are shown in Figures 31(a) and (b).

Figure 31(a) plots the fatigue-crack-growth results of X70 base and upper weld of X70. From this figure we can clearly see that the FCGR of the base metal is greater than that of the upper weld. Also, as long as it went to the stable growth region, the difference is larger at lower $\Delta K$, and the difference would decrease with increasing $\Delta K$. As the $\Delta K$ reaches 50 MPa.m$^{0.5}$, the FCGRs would become almost the same.

Figure 31(b) plots the fatigue-crack-growth results of X70 base and lower weld of X70. As can be seen in this figure, the FCGR of the base metal is almost the same as that of the lower weld, for all $\Delta K$ levels. The results suggest that the upper part and lower part of the weld metal reacted differently to cyclic loading.

The reason for this might be related to the difference in the microstructure of base and weld metals, as can be seen in Figures 32(a) and (b). Optical Microscopy (OM) was used to characterize the microstructure. The sample from the plate, including weld metal, some part of the heat-affected zone and some of the base metal, was cut, mounted, polished and etched with 2 vol.% Nital to be ready for OM. While the base metal was mainly ferrites,
the weld metal was characterized by bainite, and the grain size in the weld metal is smaller. Note that only the upper part of the weld was examined, and the lower part will be characterized in future work.

4.3.3 SEM Images of Fracture Surfaces

Figures 33-34 show the SEM images of the fracture surface of X70 base and weld metals. Figure 33 is the fracture surface at high ΔK levels, where the material was about to fail. Secondary microcracks can be clearly seen in both the (a) base-metal and (b) weld-metal images. Figure 34 shows a higher magnification of the fracture surface. Ductile striations can be seen in both figures. Also, some defects are presented in the weld metal.

4.4 Conclusions

- The FCGR of the X70 base metal increases with decreasing load levels.
- Different parts of the welds act differently to cyclic loading. The upper part of the weld showed better fatigue resistance than the lower part.
- The upper part of the weld showed greater crack-growth rates than the base metal at lower ΔK. As the ΔK goes over 50 MPa.m\(^{0.5}\), the FCGRs would become almost the same. The FCGRs of the lower weld and base metals were very similar.
- The scanning-electron-microscopy (SEM) images show evidence of secondary microcracks at high ΔK levels.
- The fracture surfaces present transgranular patterns, and ductile striation patterns can be clearly seen at higher magnifications.
Chapter 5 Neutron-Diffraction Study

5.1 Introduction

During the fatigue process, a plastic zone generally produces around the fatigue-crack tip, and the crack needs to pass through this plastic zone. Thus, fatigue-crack-growth behavior is controlled by the deformation zones that exist around the crack tip. Therefore, the size and nature of the crack-tip deformation zone have important effects on the fatigue-crack propagation. Neutron diffraction is a unique tool to study the mechanical behavior of materials. Its deep penetration and volume averaging capabilities enable the mapping of strain distributions in situ under applied loads. In the investigation, fatigue-crack-growth behavior of X52 [Fe-0.071C-1.06Mn-0.24Si-0.026Nb, weight percent (wt.%)] and X70 [Fe-0.053C-1.52Mn-0.25Cr-0.19Si-0.089Nb, weight percent (wt.%)] grade pipeline steels (original and hydrogen-charged) have been investigated to find the hydrogen effect on the fatigue-crack-propagation behavior of pipeline steels at VULCAN, Spallation Neutron Source (SNS), Oak Ridge National Laboratory (ORNL).

5.2 Experiment Details

In-situ neutron-diffraction experiments were performed using the VULCAN Engineering Diffractometer at Spallation Neutron Source (SNS), Oak Ridge National Laboratory (ORNL). The experiments were divided into two parts. One were the tensile tests, which served as the reference, and the Young’s modulus calculated from the test results would be further used as the basis of simulations. The other is the strain-mapping tests, which were to obtain the strain-evolution information at different locations around the crack tip during the loading-unloading process. Both experiments were conducted on as-received and hydrogen-charged samples.
Figure 3 shows a sketch of the neutron-diffraction geometry of the experiments. When the sample was loaded in the frame, it was carefully aligned so that the loading axis was oriented 45° to the incident neutron beam. The two stationary detector banks, which were used to record the diffraction pattern, was centered on diffractions angles of 2θ = ± 90°. Therefore, the diffraction vectors were parallel to the through-thickness (TT, perpendicular to the loading direction) and in-plane (IP, parallel to the loading direction) directions of the sample.

5.2.1 Sample Preparation for In-situ Neutron-Diffraction Experiments

5.2.1.1 Tensile Sample

Smooth bar specimens with a diameter of 5 mm were machined from the as-received X70 and X52 pipeline steel plates. The geometry followed the American Society for Testing and Materials (ASTM) Standards. Half of them were then mailed to National Institute of Standards and Technology (NIST), where they were put in a high pressure hydrogen chamber for two weeks. Then they were covered with tin in order to constrict the diffusion of hydrogen. Then they were mailed back in a low temperature environment. The other group served as the non-charged condition.

5.2.1.2 Compact-Tension (CT) Specimen

According to the American Society for Testing and Materials (ASTM) Standards E647-99, the CT specimens with a notch length of 8 mm, a width of 38.2 mm, and a thickness of 6.3 mm were machined from the as-received X70 and X52 pipeline steel plate. Then they were all pre-cracked with ΔK = 15 MPa m0.5, f = 10 Hz, R = 0.1 to a crack length of 1 mm, then switched ΔK to 11 MPa m0.5 to generate another 1 mm of crack length, resulting in a total crack length of 2 mm. The experiments were conducted using a
computer-controlled Material Test System (MTS) servohydraulic machine. Subsequently, half of the samples were mailed to the National Institute of Standards and Technology (NIST), where they were put in a high pressure hydrogen chamber for two weeks. Then they were covered with tin in order to restrict the diffusion of hydrogen. Then they were mailed back in a low temperature environment. The other group of the as-received samples served as the reference condition.

### 5.2.2 Tensile Tests

X52 and X70 pipeline steel samples were tested, the as-received and hydrogen-charged conditions. There were four samples all together. The 5-mm horizontal and 5-mm vertical slits were used to define the incident neutron beam, and the diffracted beams were collimated by a 5-mm-radial collimator in the tensile test, creating a 125 mm$^3$ gauge volume. The procedure was as follows:

1. Use load control, load the sample to 8,000 N in 30 minutes.

2. Switch to strain control, deform the sample until the strain reaches 10% in an hour (for the first sample, we deformed it to 15% in an hour and a half).

3. Unload the sample to 0 N in 20 minutes.

4. Beam was at the center of the sample, and data was collected continuously.

### 5.2.3 Strain-Mapping Tests

Compact tension (CT) specimens from X52 and X70 pipeline steels, as received and hydrogen-charged, all together four samples were employed for the in-situ neutron-diffraction strain mapping experiments at VULCAN, SNS, ORNL. Figure 35 shows the
geometry information from the neutron diffraction experiment. The 2-mm horizontal and 0.5-mm vertical slits were used to define the incident neutron beam, and the diffracted beams were collimated by a 2-mm-radial collimator in the strain mapping test, resulting in a 2 mm$^3$ gauge volume. The experiment procedure was described as follows (steps 1-3 are for hydrogen charged sample only):

1. Run the samples for 15 cycles with $f = 0.2$Hz.

2. Set the system as load control, then ramp 44s until the load went to 3000N, hold for 15 min.

3. Ramp 2.5 s to the load 0 N, hold for 15 min.

4. Detect the lattice-strain evolutions at 10 different locations from the crack tip for all four samples [- 1 mm, - 0.5 mm, 0 mm, 0.5 mm, 1 mm, 1.5 mm, 2 mm, 2.5 mm, 3 mm, and 3.5 mm] during one fatigue (loading-unloading) cycle (0 N, 750 N, 1,500 N, 2,250 N, 3,000 N, 2,250 N, 1,500 N, 750 N, and 0 N).

5. The beam was on the crack tip of the sample for steps 1-3. It took about two hours to collect data for one load level. Thus, a total of 18 hours were needed for one sample.

### 5.3 Preliminary Results and Discussion

In-plane information was used for the analysis. Figure 35 shows the stress-strain curve of the X52 sample, with or without hydrogen charged. It can be calculated from the two curves that the Young’s moduli for these two samples are basically the same. Meanwhile, the yield modulus for the hydrogen charged sample of X52 was slightly higher than that
of original sample, as shown in Figure 36. More tests are needed to confirm that hydrogen will have an influence on the sample so that the yield strength will be increased.

The Lattice parameter versus distance from the crack tip for X52 original sample was plotted in Figure 37 and Figure 38. It can be seen from the figure that the lattice parameter increases with load and varies by locations.

By comparing the lattice parameters in these two figures, we may find that the lattice parameters were similar for both samples at locations near the crack tip, while the lattice parameters for the hydrogen-charged sample were larger at other locations. One explanation for this phenomenon is that the lattice was expanded with the absorption of hydrogen. For locations near the crack, maybe the existence of compressive stress constrained the lattice expansion. Further analysis is needed to clarify this phenomenon.

5.4 Conclusions

In-situ neutron experiments were performed on pipeline-steel samples, with and without hydrogen charged. Smooth-bar specimens were used for the tensile test, while the compact tension (CT) specimen was used for the strain-mapping tests.

From the stress-strain curve of both hydrogen-charged and original sample, it was found that the yield strength was slightly increased because of the presence of hydrogen. While similar results were also found in the literature [18], other results gave opposite results that yield strength decreased due to hydrogen effect [17]. Strain mapping tests show that hydrogen does have an effect on the lattice parameter. Further investigations are needed.
Chapter 6  Conclusions and Future Work

6.1 Conclusions

- The fatigue-crack-growth experiments for Alloy B [Fe-0.05C-1.52Mn-0.12Si-0.092Nb, weight percent (wt.%)] and Alloy C (Fe-0.04C-1.61Mn-0.14Si-0.096Nb, wt.%) were performed at different frequencies (10, 1, 0.1 Hz) and different stress ratios (R = 0.1 or 0.5). It was concluded that the frequency does not influence the FCGR on these two types of steels. Also, the stress ratio seems to have an effect on the crack growth behavior. The crack propagation rate at an R ratio of 0.5 is greater than that at an R ratio of 0.1.

- The fatigue behavior of X70 base and weld metals were studied. It was found that the inhomogeneity in the weld metal leads to different fatigue behavior, when the sample was made with the notch open at different parts of the weld. While the base metal and the lower part of weld presented very similar FCGR at a certain ΔK, the upper weld showed better fatigue resistance.

- Typical ductile fatigue fracture surface was shown for all the steels in this study. Transgranular patterns and striations were clearly seen from SEM images.

- The tensile tests of pipeline-steel samples presented that the yield strength of the material was increased slightly because of the presence of hydrogen. More tests need to be performed to confirm the results. The lattice parameter as a function of distance from the crack tip of the CT specimen showed the evolution of lattice parameters within a loading-unloading cycle, and the presence of hydrogen had an
influence on this process. Further studies will help us gain more detailed understanding.

6.2 Future Work

In order to further understand the fatigue behavior of pipeline base steels and welds and to understand the influence of hydrogen, more work needs to be done, as can be seen below:

(1) Since steel pipe is made to transport hydrogen, the fatigue tests in hydrogen environment will be carried out to compare with the results in an air environment, and the influence of hydrogen will be evaluated.

(2) Further analysis of the neutron-diffraction experiments results need to be done to study the influence of hydrogen on the crack tip.

(3) A micro-hardness mapping test will be performed to characterize the inhomogeneity of the weld region of pipeline steel.

(4) A synchrotron experiment has been done to detect the plastic zone evolution upon loading-unloading, and the results are being analyzed.

(5) The residual stress of the weld plays an important role in the mechanical behavior of steel welds. A neutron-diffraction experiment to characterize the residual stress of the weld plate will be proposed.

(6) Duplicate tests need to be performed to confirm the previous results.

(7) Efforts will be made to simulate the fatigue behavior of pipeline steels in hydrogen atmosphere.

(8) Papers will be written on previous results and future findings.

Vita

Bilin Chen was born in Yiyang, Hunan, China, to the parents of Zengyi Chen and Xuefei Yi, with Bihai Chen as his younger brother. He graduated from No.1 Middle School of Yiyang in 2006. He graduated with a Bachelor of Engineering degree from the Department of Materials Science and Engineering at Central South University in June 2010. He joined the Graduate Program at the University of Tennessee, Knoxville in August 2010 and received a Master of Science degree in Materials Science and Engineering in August 2013.
